Our center has previously published a 4.4% figure for loss of desired pregnancies when amniocentesis was performed at <15 weeks' gestation.[3] That study was criticized for being heavily weighted with patients who were at 13 and 14 weeks' gestation. A comparable figure for this study is 6.2%.

There are now other studies in the literature evaluating early amniocentesis. Elejalde et al.[11] reported the loss of four of 77 (5.2%) fetuses <13 weeks within 2 weeks of amniocentesis. Nevin et al.[12] in a small series lost no fetuses between 9 and 12 weeks ($N = 25$). Benacerraf et al.[13] reported no losses in 100 patients at <15 weeks after a 5-week follow-up period.

The establishment of a procedural risk factor for comparison with other studies and for patient counseling is important yet difficult. All prenatal diagnostic procedures are performed against a certain background of spontaneous abortion. The earlier a procedure is performed, the higher is that loss rate and the longer is the opportunity for subsequent spontaneous loss. Lack of physician experience, poor reproductive history, and increasing patient age have all been shown to be possible factors in increased loss rates.

It has generally been accepted that 15% to 20% of recognized pregnancies result in spontaneous abortion before 20 weeks' gestation. Liu et al.[14] reported an overall 2.7% spontaneous abortion rate in pregnancies found to be ultrasonographically normal before 14 weeks, with 1.5% occurring before 16 weeks' gestation. A higher loss rate was seen in primigravid patients (1.8%) and threatened abortion patients (38%). Gilmore and McNay[15] and Wilson et al.[16] reported similar findings with an overall loss rate of 2.1% and 2.13%, respectively. The 1976 National Institute of Child Health and Human Development study demonstrated a 3.2% spontaneous abortion loss rate in their control group of women matched for race, gravidity, and income.[5]

Our overall loss rate of ultrasonographically normal pregnancies was 3.4% (32/936). If one accepts a background loss rate of 2.1%, we are left with a difference of 1.3%. At least 2% ($n = 19$) of the losses (four stillbirths or neonatal deaths, 14 losses >2 weeks after the procedure, and one before 2 weeks) had one or more documented normal visits with their referring obstetrician or another possible cause of the loss. Evaluation of these data would suggest that in experienced hands amniocentesis at ≤12.8 weeks may have only a slightly, if any, increased risk of loss when compared with standard amniocentesis.

Technically, continuous ultrasonographically guided early amniocentesis is easy to perform. The experienced physician will reschedule those patients who have amnion-chorion separation and seemingly no available area of amnion attachment to the uterine wall, because they are more likely to subsequently have a leakage of amniotic fluid. Obesity, recent bleeding and cramping, a retroverted uterus, bladder or bowel superimposition over the uterus, and decreased fluid volume are also reasons to consider rescheduling amniocentesis in some patients.

In summary, it would appear that amniocentesis at 12 weeks is a viable option for patients desiring earlier prenatal genetic diagnostic information.

We thank Mrs. Sherry Stroud for assistance in data collection and compilation and in manuscript preparation.

Discussion

Dr. Gerald M. Shefren, Palo Alto, California. In 1989 Dr. Hanson presented to this society a series of ultrasonographically guided early amniocenteses in singleton pregnancies. In that series of 308 patients only 70 were listed as being <13 weeks' gestation. In the series presented the authors have retrospectively reviewed 936 patients of <13 weeks' gestation among 8165 amniocentesis procedures performed from 1986 to 1990. Dr. Hanson is to be congratulated, for this represents by far the largest series reported of first-trimester amniocenteses.

Comparison of these two reports shows a lower complication rate in the larger series reported here and only a slightly higher rate than in the midtrimester group when corrected for spontaneous background loss. Miscarriage within 2 weeks of the procedure dropped from 1.7% to 0.7%. Total procedural losses decreased from 4.7% to 3.4%. Success with first needle insertion increased from 88.5% to 97%. It seems clear that even experienced operators with midtrimester amniocenteses will have higher complication rates at first and lower rates as they gain experience.

One interesting difference was seen in the outcomes of patients experiencing fluid loss after the procedure. In the first series only one of eight had a fetal death. In this latest series four of 10, or 40%, of those with leakage of amnionic fluid experienced a fetal death within 2 weeks. This comparison appears to carry a much graver prognosis in first-trimester amniocenteses than it does in the midtrimester.

If the safety and accuracy of diagnosis can be assured with early amniocentesis, it would clearly invite obstetricians and their patients to consider it in place of chorionic villus sampling. At this time there are >60,000 patients who have undergone chorionic villus sampling worldwide. There have been several international multicenter, prospective, randomized studies published. Many, like the Medical Research Council report, compared chorionic villus sampling with midtrimester amniocentesis. Most studies showed some increased risk of chorionic villus sampling over midtrimester amniocenteses of 1% to 2% in total pregnancy losses. However, accuracy in detecting mosaicism, false-positive and false-negative rates, and the ability to measure α-fetoprotein and acetyl-cholinesterase clearly favor amniocentesis.

Comparing the results of the prospective randomized studies with the results presented by Dr. Hanson would be difficult, especially as they relate to patient selection. It seems possible that the patients in this report may have been selected as low risk by the referring obstetricians or the patient herself simply because it was a nonstandard approach.

I support the suggestion of other authors that until early amniocentesis is subjected to a large, randomized, prospective study the routine referral of patients for early amniocentesis seems premature. With that caveat in mind, the data in this series seem to support Dr. Hanson's conclusion that early amniocentesis appears to be a viable option for patients seeking first-trimester genetic diagnosis.

I have several questions. Do you have any data on the percentage of patients who would need to be rescheduled for technical reasons if all amniocenteses were attempted at <13 weeks' gestation? Because the mean amount of amniotic fluid is about 65 ml when most of the patients in your series underwent the procedure and if one removes 1 ml per week of gestation, some patients would have an acute amniotic fluid loss of 20%. Have you rescanned any of these patients over an extended time after the tap to see how long it may take to reaccumulate the lost fluid, if in fact it can be quantified at all?

Dr. Bruce B. Rolf, Los Angeles, California. What about the six abnormalities you missed?

Dr. Hanson (Closing). Dr. Shefren, because of our wide catchment area, we have some patients who traveled long distances and for them rescheduling is a real problem. Our rescheduling rate is <2% because our staff thoroughly screen the patients. If we know that the patient has a retroverted uterus or weighs >250 pounds, we schedule the procedure later in pregnancy.

In regard to amniotic volume, we have an unspoken agreement with the sonographers that if they see any change in amniotic cavity size, they tell me and I stop.

Dr. Rolf, I left out all discussion of undiagnosed abnormalities such as hydrocephalus and cleft lip and palate because we have discussed them in other articles. You would not expect to detect hydrocephalus before 18 to 20 weeks and cleft lip and palate are difficult to detect at 12 weeks. To the best of my knowledge, no abnormality that should have been picked up was missed by ultrasonography associated with any of the early amniocentesis procedures I have reported.

TRANSACTIONS OF THE FIFTY-NINTH ANNUAL MEETING OF THE CENTRAL ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS

Suffer the little children

Presidential address

James P. Youngblood, MD
Kansas City, Missouri

As I set about planning this address, I reviewed many of the recent addresses given by our esteemed past presidents. They are generally in one of three categories: historic, scientific, or philosophic. They have nearly always been of a personal nature, to a greater or lesser degree, revealing something of the inner character of the speaker. Dr. Russell Malinak's address last year was especially stirring and memorable. I recall one of our members asking me immediately after the talk whether I felt that I could top it this year. Of course, I won't be able to, and I won't even try. But I hope at the end I will have given you some food for thought, and perhaps you'll also know a little more about me.

My talk is more of the philosophic type, and I think it will reveal a little of how I think and what has become very important to me over the years.

The title of this address is "Suffer the Little Children. . . ." What do I mean by that? I think that most of you are aware that this is from the New Testament, the Gospel according to Mark, chapter 10, verse 14. "Suffer the little children to come unto me and forbid them not, for such is the Kingdom of God." After preaching all day, Jesus is tired and is resting and the little children in the area have come for his words and his blessing, and his disciples are trying to keep them from him so that he may rest. In this case, Jesus uses the term *suffer* to mean *permit.* He indicates that the children have a priority higher than any need that he may have for rest. Indeed, he indicates their helplessness and innocence in the words "for such is the Kingdom of God."

I have used the word *suffer* in a double context in this address, because the children in our world and in our country do suffer. And, of course, they are innocent. By now you are certainly aware that we have a problem with infant mortality in this country and that it is a national embarrassment. The richest nation on earth, now the only super power, with the most advanced medical technology, which spends 11%[1] of its gross national product on health care, ranks nineteenth to twenty-second[2] in the world in perinatal mortality. The most recent figures indicate that the overall perinatal mortality in the United States in 1988 was 13.7.[3] This means that per 1000 live births 13.7 babies die either before or during birth or within the first 28 days of life after birth. In 1990 in the county in which I live the perinatal mortality rate was 13.0[3] overall and 21.4 for blacks.[4] This is pathetic.

So here we go again—another talk about perinatal mortality and America-bashing because we're doing such a lousy job. I'm sorry, but the problem is severe and must be kept in the public consciousness. But we're not all that bad. We are doing some things to turn the problem around and we are making progress. But more must be done.

I know that you are concerned that this talk will be a reiteration of Dr. Malinak's eloquent address last year.[5] You must forgive me for having chosen the same topic, but realize that this has been my main area of concentration for the past 7 years and I have thought long and deeply about this problem. I may cover some of the same ground, but I think you'll see that we have somewhat divergent views in the solution of the problem and therefore I feel it merits exploration. In the long run I do not wish you to consider this a rebuttal of Dr. Malinak's address but rather an exploration and possible expansion.

While in the private practice of obstetrics and gynecology for 20 years, I was aware that there was a perinatal mortality problem. But it was in the inner city, and although I frequently attended clinics in the inner city, I was not completely aware of how extensive and pervasive the problem was. It wasn't that I didn't care, it was that I was just unable to interact in a meaningful way.

Seven years ago, I undertook the chairmanship of an obstetrics and gynecology department in an inner-city public hospital. I was unprepared for what awaited.

From the Department of Obstetrics and Gynecology, University of Missouri-Kansas City School of Medicine, Truman Medical Center.
Presented at the Fifty-ninth Annual Meeting of the Central Association of Obstetricians and Gynecologists, Colorado Springs, Colorado, October 10-12, 1991.

The indigent and working-poor population had been increasing—Nutrition was poor, disease of all kinds was rampant, and medical complications of pregnancy were numerous. Resources of all kinds were inadequate to meet these demands. The low-birth-weight rate at our hospital was 15% as compared with a national average of 6.9%. Then came Medicaid expansion and we were able to increase staffing and more actively apply our interventions, especially for so-called high-risk pregnancies. But, in spite of all our efforts, the low-birth-weight rate remained at 15%. Consequently, we developed the premise that risk assessment for pregnancy as it was done in most institutions was invalid in our institution. It was our impression that the patients we called routine patients were, indeed, all at high risk. With the support of a 2-year grant from The March of Dimes, we set about proving this premise. We studied 300 routine patients in the study group against 300 similar routine patients in the control group. The study group was intensively educated, with emphasis on things such as awareness of premature contractions, health and diet, and education regarding smoking, and drug and alcohol abuse. Socioeconomic problems were more intensely addressed. In other words the study group of routine patients was treated as high risk. Amazingly, the low-birth-weight rate in the routine study group, who had intensive prenatal care and education, was 7.3%, whereas the rate in the so-called routine control group was 14.8%. Therefore a decrease of 7.5% in the low-birth-weight rate occurred.[6] Although it was a small study, the numbers were compelling and I was able to convince our hospital director to increase our staffing of nurse practitioners, nurses, health care educators, nutritionists, and social workers in our obstetric clinic so that we could intensify our care across the board for all of our patients. In January 1991 we instituted this plan and look forward to a positive report on the results in the near future.

But intensity of prenatal care is not the only answer. Prenatal care is carried on within the institutional walls or doctors' offices and does not address the problems of access, transportation, economics, and the social and psychologic difficulties of the patient population. Nor does it address the role of poverty—poverty rooted in habits and character traits—"behavioral poverty" George Will called it in his recent syndicated column of Sept. 29, 1991.[7] Nor does it address the teenage pregnancy problem and particularly the cultural sensitivity of our various racial and ethnic subgroups. Yet, in addition, we must also stress responsible parenting. Too long have we witnessed teenagers spring and bearing three or four children before age 20. Not only safe sex but responsible sex must be encouraged as in the American College of Obstetricians and Gynecologists' "I Intend" program. Finally, we must address the role of government, industry, and the medical profession itself.

In this country we tend to excuse our poor performance with perinatal mortality relative to European countries by stating that we're comparing apples and oranges. Societies in Scandinavia, Germany, France, and England are all homogeneous, whereas in the United States we have a much more heterogeneous society composed of various cultures, ethnic backgrounds, and races. We somehow rationalize that this prevents adequate prenatal care and universal access to such care. The major difference is that in all of the European countries and in Japan universal access to prenatal care is not only available but mandated by the governments of these countries.

In the 1989 report of the United States Public Health Service expert panel on "Content of prenatal care," many factors that may affect perinatal mortality were cataloged.[8] Without going into great detail, these can be subdivided into medical disorders before pregnancy, such as hypertension and diabetes, and specific pregnancy conditions or hazards, such as preeclampsia and infection. There also are psychosocial risk factors, including being a single parent, having a limited formal education, and living in poverty. This leads to the next item of socioeconomic status, which includes occupation, education level, housing, income, marital status, and nutritional resources. Seldom considered but extremely important are psychologic factors such as limited maternal support networks and increased levels of stress because of pregnancy, emotional disorders, and, of course, pregnancy ambivalence. Increasingly, adverse health behaviors have contributed to perinatal mortality and these include, as we well know, drug and alcohol abuse and smoking.

I submit that we can address the medical problems associated with pregnancy and are doing so within our institutions when we have early registration into the care system by our mothers. It is the socioeconomic and psychosocial factors and the cultural and ethnic factors that prevent us from applying our medical technology to the fullest with the expectation of good outcome. We must get out of the institutions and into the community to address these problems. We must begin education and provide resources to attract women not only to early prenatal care but even to preconception care. It is imperative that we form a partnership of influencing factors, government, industry, and the health care community and women themselves who can work together to address this problem of high perinatal mortality. Let's take a look at what these entities can do.

What can government do? In 1986 Congress formed the National Commission to Prevent Infant Mortality. Its charge was to create a national strategic plan to reduce infant mortality and morbidity in the United

States. The Commission includes some members of Congress, the Secretary of Health and Human Services, and the Comptroller General of the United States. One of the unique programs this National Commission has developed is the concept of home visiting, especially by resource mothers. Resource mothers are women selected from the community who have evident helping skills and who have been successful mothers. They receive training in health, social services, and counseling to enable them to help disadvantaged young mothers, usually teenagers, get early prenatal care and reduce or eliminate unhealthy behaviors, such as smoking, drinking, and other substance abuse. In addition, these resource mothers help prepare the patients for labor and delivery and the needs of a newborn. These women are generally neighbors and friends of the young women they visit and therefore are culturally sensitive and aware of not only their health needs but also their psychosocial and economic needs. They also visit the mothers and babies after delivery and ensure the infants receive regular checkups and that the health of mother and baby is enhanced and ensured. Where these programs have been established, there has been a marked lowering of the low-birth-weight rate.[9] We are working now to promote this kind of activity in our own area and anticipate such activity catching on throughout the nation.

What can we expect from Industry? You should know that in all of the countries I've mentioned, in Europe and Japan, industry in some way or another subsidizes pregnant women. In France women are paid their normal salaries for 6 weeks before delivery and 6 months after delivery. Also, a doctor may prescribe additional compensated rest whenever indicated.[10] How can they afford to do this? The question should be, how can we in the United States afford not to subsidize our pregnant women? You may be surprised to know that a few enlightened companies in this country are already subsidizing pregnancy. Mr. Joseph Taylor,[11] plant manager of Sunbeam Industries, Coushatta, La., is one of the early leaders in this kind of support for pregnancy.

What can we expect of medicine? What can we as obstetricians-gynecologists do to reduce infant mortality in the United States? Do we need to change our whole health care system? I think not. As Dr. Malinak so eloquently expressed in his address last year,[5] we have the finest health care system in the world, bar none. Our problem is getting that health care to those who need it in a timely manner to prevent low-birth-weight infants and high perinatal mortality.

There are things we can do. In his presidential address, our Immediate Past President of The American College of Obstetricians and Gynecologists, Ezra Davidson, presented a strategy to reduce infant mortality. Briefly, his strategy is to mimic the maternal mortality review committees that we used so effectively in the 30s, 40s, 50s, and 60s to reduce maternal mortality to a number <1 in this country. Dr. Davidson feels that similar local review committees should be established and every perinatal death should be reviewed as to cause and preventability. He feels, and justifably so, that such intensive peer review will reveal numerous strategies to respond to locally identified factors.[11]

I would strongly urge that you not only be active members of such committees in your area but even spearhead the formation of such committees if they currently do not exist. Nearly all of us belong to local obstetrics and gynecology societies or city or county medical societies whose resources could be used for this effort.

And what should we expect of our nation's mothers to help reduce perinatal mortality in the United States? They must be educated as to the necessity of early prenatal care and even of preconceptional care. They must be encouraged to enter the health care system at an early age, in grade school if possible. They should register early for prenatal care because pregnancy may be a delicate condition in their particular case. They may need special care and special interventions to ensure a good outcome for themselves and their babies. Adverse health behavior should be curtailed or modified. Smoking, drinking, and illicit drug use should cease as proper nutrition is emphasized. Many workplace and pregnancy-related studies that have been done link working conditions to increased adverse outcomes in pregnancy. For example, a job requiring standing all day is much more likely to produce preterm labor than a job requiring only part-time, upright working conditions.[12] Pregnant women and their employers need to be aware of the implications of their workplace situation and adjust accordingly.

Finally, in my mind there is really only one comprehensive and satisfactory solution for reducing perinatal mortality in this country. Universal access to early prenatal care! All of the factors I've just mentioned should be addressed, but universal access is the absolute necessity. All of our medical and social interventions are useless unless they are accessible. We are all aware that 37 million people in this country have no health insurance. Naturally, most of these people are young and many of them are women in the reproductive age group. Medicaid is addressing the needs of the very poor but not the working poor. We must address the needs of all pregnant women. You know we have a peculiar mindset in this country that everyone must adhere to the "pay-as-you-go" format for health care regardless of economic situation.

Have you ever considered that there is a very large

segment of our population that has to jump through only one hoop to have health care provided? There is no asset testing, no one's bank account is examined, there are no qualifications save one—you must be 65. Of course, I'm talking about Medicare. I remember in 1965 I had just started in practice and was appalled that Congress enacted the Medicare Act, feeling it would be the downfall of medicine. You'll recall that organized medicine came screaming and kicking into the Medicare reality. Obviously, its not a perfect system and is rife with problems and even corruption, yet it continues to be one of the more humane things that our society has done for its elderly.

As a matter of fact, in 1987 combined Medicare and Medicaid health care for the aged and disabled came to 114 billion dollars, or 23% of the health care dollar, as opposed to only 6 billion, or 2.5%, provided for maternal health care.[13] Are we emphasizing the wrong age group? Triple bypass surgery in a 75-year-old person costs $50,000; prenatal care costs $500.

I would propose that government, industry (including the insurance industry), and the medical profession form a partnership to produce a maternity insurance plan that would be available for all. The only requirement to enter the health care system to receive prenatal care would be a positive pregnancy test. No other hoops need be jumped through because no extensive application forms need be reviewed and there would be no asset testing. Imagine the decrease in the bureaucracy now used to administer Medicaid. Any pregnant woman regardless of race, ethnic background, or social status would be eligible for this care.

But, given the problems obstetricians currently have with Medicaid, such as low and slow reimbursement and the interminable forms and red tape, why would they buy into this plan?

First, organized medicine must negotiate a realistic global fee for prenatal care and delivery. This fee must take into account that many of the new and previously uninsured will be at high risk, as I have already outlined.

Second, because a positive pregnancy test allows immediate and early access to care, any necessary documentation and paper work can be accomplished throughout the course of pregnancy, thus ensuring prompt payment on completion of care.

How would a newly pregnant woman have access to care? She would simply obtain proof of pregnancy from any recognized health care provider (e.g., hospital, clinic, or her own physician). She would immediately receive a voucher for prenatal care by her provider of choice.

What about the woman who desires more than average amenities? Because the vouchers would be equal in value, she would need to personally supplement the reimbursement required for these amenities. As you know, this same system is currently used in European countries.

What should we call this plan? How about "Maternacare"? Call it what you will, but whatever you call it, it is progress for humankind and maternal and infant welfare.

Perhaps I've made this too simplistic. Believe me, I know that problems will ensue. Institution of this kind of system will strain the resources of the prenatal health care system as we know it today. When we instituted our own new program as I previously outlined to you, so markedly increased was patient interest and awareness that early registration and frequency of visits increased to the point that we swamped the system. Our physicians, both resident and attending, were unable to handle the load, and we had to hire additional physician extenders, such as nurse practitioners and physician aides. But this is already going on in many large obstetric groups and health maintenance organizations. I have personal knowledge in our own area of private practice groups that have hired nutritionists, nurse practitioners, and even midwives to help them with the enhanced prenatal care that they wish to deliver. Obstetricians will need to become comfortable with the idea that they will need the help of other professional health care providers to maximize their efficacy in driving down perinatal mortality in this country.

As I was writing this article, I mentioned this concept to several friends and associates, not necessarily physicians, and, to a person, the first question they asked was, "Who would pay for it?" Well, obviously, you and I would pay one way or another, but we already pay for Medicare and Medicaid. We pay for national defense, and we pay for fire and police protection and wildlife conservation. And how about the savings and loan bailout—the last estimate I read 2 weeks ago was 160 billion dollars! What I am asking for is peanuts!

Why not pay for our single greatest resource, our newborn infants? And, would it be very expensive? Yes, but it certainly is expensive now. Consider that a premature infant of 2 pounds who stays in the hospital up to 3 months may incur medical costs of $50,000 to $100,000 and possibly a lifelong cost of $400,000 to $1,000,000 if neurologic deficits are incurred. Consider that there are 280,000 low-birth-weight infants born annually[5] and each of them incurs on average $10,000 in additional medical costs before they can leave the hospital. This comes to a total of $2.8 billion. Consider if we could lower the low-birth-weight rate by 1% in this country, the savings would be $400,000,000 annually. If we could get our preterm delivery rate down to that of France, which is slightly over 4%,[15] the savings

would be more than $1 billion. This savings plus what is currently spent by government sources, insurance premiums, and private pay would come close to paying for the entire cost of universal access to prenatal care. Whatever the cost, the time has come for this nation to get its priorities straight and one of them should be a reduction in this terrible infant mortality that we continue to have.

National mindsets can be overcome. Even global mindsets can be overcome.

Consider Semmelweiss' realization that it was the unclean obstetrician who was the cause of puerperal sepsis—childbed fever. It was 30 years before his simple recommendations for antisepsis were accepted, after he had been driven mad by his critics and detractors.

Sometimes the simplest ideas may have most profound effects!

Surely we can overcome this mindset that is keeping us from enjoying our most precious resource—the infants and children of our country.

Suffer the little children to come unto us—healthy. And on time! Suffer the little children to suffer no more!

CURRENT PROBLEMS IN OBSTETRICS, GYNECOLOGY AND FERTILITY

Editor-in-Chief: Robert L. Barbieri, MD
State University of
New York at Stony Brook

Current Problems in Obstetrics, Gynecology and Fertility brings you the authoritative, practical information you need to stay current in your specialty and to provide the best possible care to patients.

- Each bimonthly issue provides in-depth, monograph-length coverage (40-60 pages) of a clinical topic of vital interest to practitioners today.
- Topics are selected for relevance to your daily practice: preconceptual counseling, infertility, endocrine problems, high-risk obstetrics, diagnosis and treatment of primary and secondary amenorrhea, pediatric and adolescent gynecology, and more.
- Authors are selected for their expertise; you'll benefit from their balanced perspective on the topic and their wealth of clinical experience.
- Each article is extensively referenced, saving you hours of library research.

Stay at the forefront of your specialty! Subscribe today by returning the order form or by calling our toll-free number.

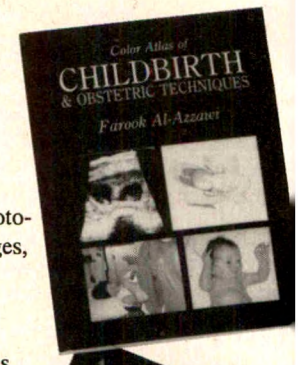
Important subject.
Important hands-on methodology.

Exceptional skills are born of exceptional training. And there are none better than skills gained on a live, pregnant patient. For the last decade, we've emphasized not only the *how* of the science of ultrasound, but also the *why* behind each technique.

We offer comprehensive training seminars in abdominal, vascular, obstetric/pelvic, and cardiac ultrasound. And, for your convenience, our seminars are held in major cities across the United States as well as at our modern new facility in the Dallas area. We offer a variety of two-, three-, and five-day programs at reasonable fees. Classes are roughly half theory and half intensive hands-on training. Class size is strictly limited, and postconference support is free to our guests--*forever.*

All of our seminars are SDMS-approved for CEUs. Call KMA 24 hours a day for a free information kit that tells you about us and any of the twenty different seminars we conduct regularly. For exceptional abdominal/obstetric/pelvic imaging, put your hand in our hands. Just call (214) 402-8250.



Hands-On Abdominal Imaging
July 20-24, Sept 14-18, Nov 2-6, Dallas.
Advanced Abdominal Imaging Interpretation
July 24-25, Dallas.
Advanced Obstetric/Pelvic Imaging Interpretation
July 31-August 1, Dallas.
Hands-On Obstetric/Pelvic Imaging
July 27-31, Sept 21-25, Nov 9-13, Dallas.

Anatomic aspects of vaginal eversion after hysterectomy

John O.L. DeLancey, MD
Ann Arbor, Michigan

OBJECTIVE: Our aim was to understand how vaginal eversion after hysterectomy differs from other forms of prolapse.
STUDY DESIGN: The role of individual structures involved in vaginal support was studied by pelvic dissection of 61 cadavers. Serial cross sections from 13 additional cadavers were examined.
RESULTS: The upper third of the vagina (level I) is suspended from the pelvic walls by vertical fibers of the paracolpium, which is a continuation of the cardinal ligament. In the middle third of the vagina (level II) the paracolpium attaches the vagina laterally to the arcus tendineus and fascia of the levator ani muscles. The vagina's lower third fuses with the perineal membrane, levator ani muscles, and perineal body (level III). Dissection reveals that the paracolpium's vertical fibers in level I prevented prolapse of the vaginal apex and vaginal eversion.
CONCLUSIONS: The paracolpium in level I forms the critical factor that differentiates vaginal eversion from posthysterectomy cystocele-rectocele or enterocele in which the vaginal apex remains well suspended. (Am J Obstet Gynecol 1992;166:1717-28.)

Key words: Vaginal prolapse, vaginal eversion, hysterectomy

Vaginal eversion occurs after hysterectomy when the apex of the vagina descends below the introitus so that the vagina turns inside out. In recent years this problem has become a topic of considerable concern. In spite of our generally good success in treating vaginal eversion[1-3] we know little about its cause and prevention. Vaginal eversion is usually thought of as a problem caused by an enterocele that was not repaired at the time of vaginal hysterectomy for prolapse,[4] yet in half of the patients with posthysterectomy vaginal eversion the condition develops after an abdominal hysterectomy that was performed for reasons other than prolapse.[1, 4] In addition, this theory does not explain why some patients have an enterocele with a well-supported vaginal apex after hysterectomy whereas others have both an enterocele and an eversion of the vagina. These questions highlight the importance of knowing the specific anatomic defect that is responsible for vaginal eversion.

Many investigators have looked at the structural changes that are associated with uterine prolapse, cystocele, or rectocele, and these studies have been summarized elsewhere.[5] None of these reports have directly studied the anatomy of vaginal support as it relates to the problem of vaginal eversion after hysterectomy. It is possible to piece together some aspects of this anatomy by gathering the observations of several authors; however, this eclectic collection is characterized by controversy, conflict, and confusion[6, 7] and justifies the need for a specific examination of vaginal support after hysterectomy. The aim in studying vaginal support was to gain information that would help explain the anatomic difference between women with vaginal eversion and those with cystocele, rectocele, or enterocele after hysterectomy but in whom the apex of the vagina remained well supported.

Material and methods

Dissections. Several types of observation were used for this study to avoid the errors that can arise from artifacts present in any single technique of anatomic investigation. Vaginal support was examined in cadavers that had previously undergone hysterectomy, as well as in those with the uterus in place, so that we could study both the relationship of vaginal support to uterine support and the support of the vagina seen after hysterectomy (Table I). Dissections, which were performed on the pelvic viscera and the pelvic walls, focused on the connective tissue and muscles in the region bounded laterally by the bony pelvis and extending from the sacral promontory to the vulvar skin.

The importance of specific structures to vaginal support was studied in selected cadavers that were in an upright position, as if an individual were standing. Isolated portions of the vagina were forced toward the introitus for study of the structures that prevented prolapse or eversion from occurring. Special attention was paid to the tissues that resisted eversion of the vagina

in cadavers with previous hysterectomy. Examination of cadavers that were in the upright position permitted the suspensory apparatus to be examined in the orientation in which it is called on to support the vagina (i.e., the standing position). This technique was found to be critical in the correct interpretation of the role that each part of the vaginal support system plays in holding the vagina in place.

The cadavers used in this study included both those fixed by the traditional injection technique and ones fixed by immersion. The immersion method was used to eliminate the distortion created by injection embalming. The normality of the spatial relationships in cadavers fixed by immersion was confirmed by comparing them with topographic studies of living individuals with normal support that are available in the literature.[8]

Serial cross sections. Both histologic and whole-pelvis cross sections were studied. The serial histologic sections were made available to me by Dr. Thomas Oelrich and have been described in previous works.[9, 10] They included 1500 sections from eight individuals 0 to 37 years old. These were used to confirm the histologic nature of the tissues identified in the whole-pelvis cross sections and to determine the specific direction of various fibers within the pelvis. Serial whole-pelvis cross sections were made from frozen cadavers fixed by immersion, as indicated in Table II. Sections were cut at intervals varying from 5 mm to 2 cm an stored in formalin.

Results

Overview. The bladder, uterus, vagina, and rectum are all attached to the pelvic walls by a network of connective tissue strands that are collectively called the endopelvic fasciae. Although the connective tissue of the endopelvic fascia is one continuous unit, it has distinct regions that are given individual names. For example, the structures that attach the uterus to the pelvic walls (i.e., the broad, cardinal, and uterosacral ligaments) are called the parametria. Similar tissues attach the vagina to the pelvic walls, and these are referred to as the paracolpium (Fig. 1). They are continuous with the cardinal and uterosacral ligaments when the uterus is in situ.

The structures that support the vagina can be divided into three levels that correspond to differing areas of support (Fig. 2 and Table III). The portion of the vagina adjacent to the cervix is suspended from above (level I: suspension) by the relatively long connective tissue fibers of the upper paracolpium. In the midportion of the vagina the paracolpium becomes shorter and attaches the vaginal wall laterally to the pelvic walls (level II: attachment). Near the introitus the vagina is fused laterally to the levator ani muscles and posteriorly to the perineal body while anteriorly it blends with the urethra (level III: fusion) (Fig. 3). In level III there is no intervening paracolpium between the vagina and its adjacent structures, contrary to the situation in levels I and II.

Anatomic observations. The cephalic 2 to 3 cm portion of the vagina constitutes level I. The fibers of the paracolpium suspend this part of the vagina and arise over a broad area originating from the region of the greater sciatic foramen over the piriformis muscles, from the pelvic bones in the region of the sacroiliac articulation, and from the lateral sacrum. These fibers are primarily vertical in orientation (Fig. 4), but some also proceed dorsally from the vagina toward the sacrum in a more horizontal direction when viewed in the standing position (Fig. 5). At the lateral margin of the vagina the fibers of the paracolpium diverge to envelop its anterior and posterior surfaces (Fig. 5). As is true of other visceral ligaments, these suspensory fibers are composed of perivascular connective tissue, blood and lymphatic vessels, and nerves. Within this meshwork there is also a considerable amount of nonvascular smooth muscle.

Structurally, the paracolpium's suspensory fibers in level I converge from their broad origin on the lateral pelvic walls and sacrum to their localized attachment to the lateral walls of the vagina. In effect the upper portion of the vagina hangs from the pelvic walls and sacrum. When downward force is applied to the vaginal apex in an attempt to cause its eversion, the suspensory fibers of the paracolpium prevent this from happening (Fig. 6, *A*). Transecting the paracolpium in this region allows the upper vagina to evert into the lower vagina when downward force is applied (Fig. 6, *B*). Upward traction on the vaginal apex in level I elongates this

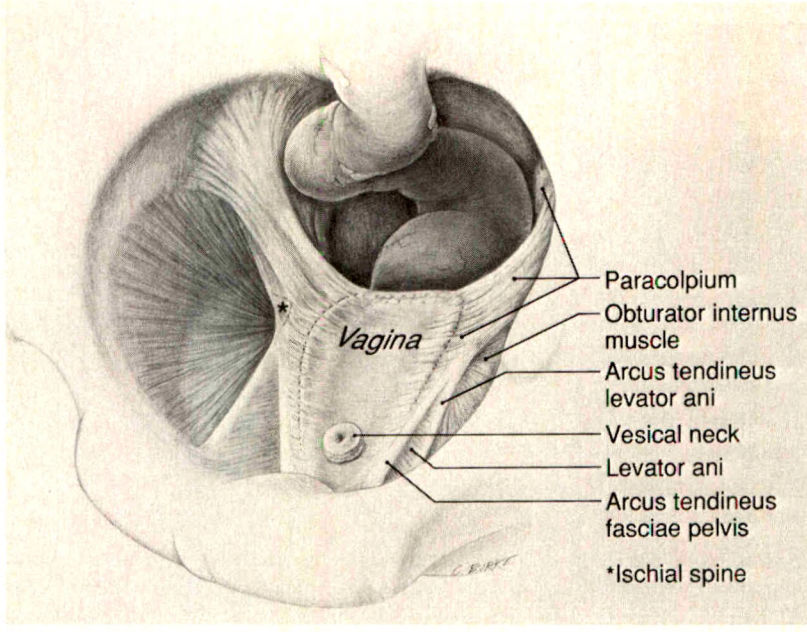

Fig. 1. Vagina and supportive structures drawn from dissection of 56-year-old cadaver after hysterectomy. Bladder has been removed above vesical neck. Paracolpium extends along lateral wall of vagina.

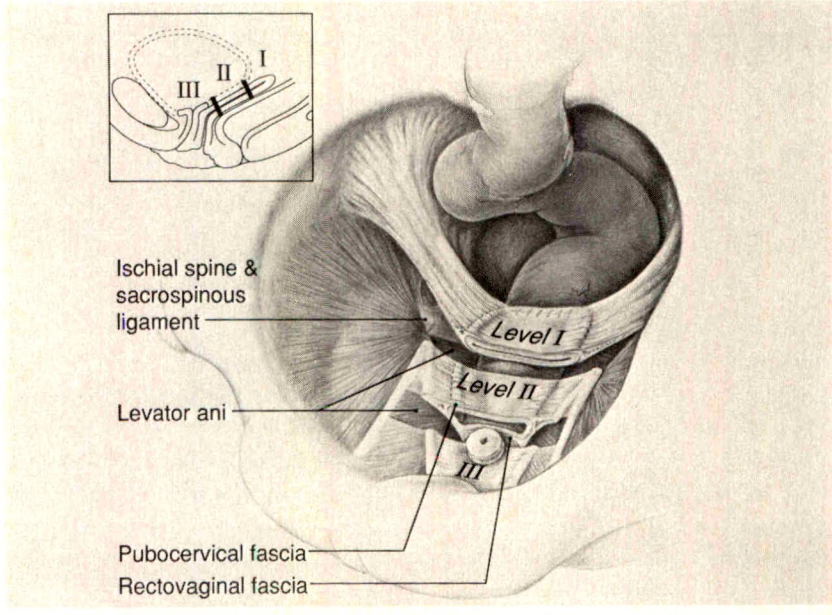

Fig. 2. Level I (suspension) and level II (attachment). In level I paracolpium suspends vagina from lateral pelvic walls. Fibers of level I extend both vertically and also posteriorly toward sacrum. In level II vagina is attached to arcus tendineus fasciae of pelvis and superior fascia of levator ani muscles.

portion of the vagina in a cephalic direction. This motion is not resisted by the suspensory fibers but is limited only by the vaginal wall's ability to stretch.

In level II the vagina comes closer to the pelvic wall, the length of the paracolpium becomes shorter, and the nature of the vagina's connections changes from one of suspension to one of lateral attachment (Fig. 3). The connective tissue that attaches the vagina to the pelvic walls is composed of smooth muscle and a mixture of collagen and elastin. It is more dense than that of the cardinal and uterosacral ligament complex. The blood vessels, lymphatics, and nerves that characterize the

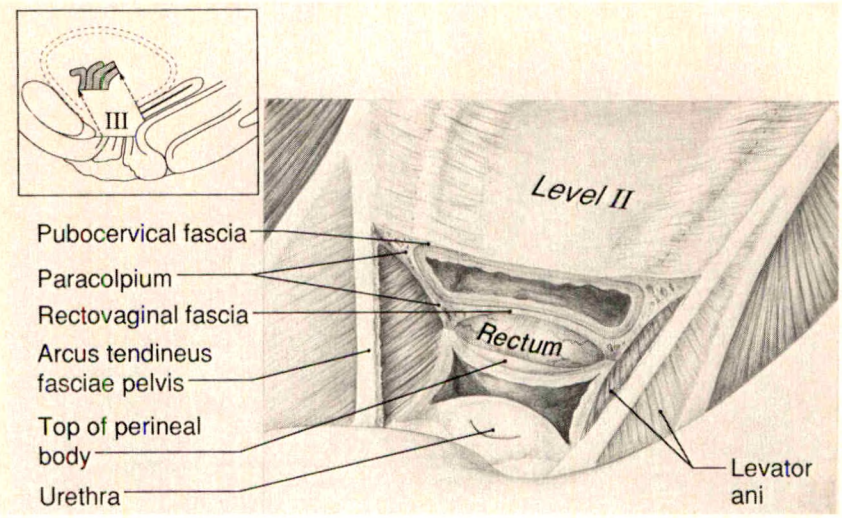

Fig. 3. Detail of levels II and III are shown after wedge of upper urethra and anterior vaginal wall has been removed *(shaded area of inset)*, exposing anterior surface of rectum. In level III vagina is fused to medial surface of levator ani muscles, urethra, and perineal body. Anterior surface of vagina and its attachment to arcus tendineus fasciae of pelvis forms pubocervical fascia, while posterior surface, through its attachment to superior fascia of levator ani muscles, forms rectovaginal fascia.

Table III. Clinical-anatomic correlation

Level	*Structure*	*Function*	*Effect of damage*
Level I: Suspension	Upper paracolpium	Suspends apex to pelvic walls	Prolapse of vaginal apex
Level II: Attachment	Lower paracolpium		
	Pubocervical fascia	Supports bladder and vesical neck	Cystocele-urethrocele
	Rectovaginal fascia	Prevents anterior expansion of rectum	Rectocele
Level III: Fusion	Fusion to perineal membrane, perineal body, musculi levator ani	Fixes vagina to adjacent structures	Urethrocele or deficient perineal body

upper paracolpium continue along the lateral margin of the vagina in this region.

The attachment of each lateral margin of the vagina to the pelvic wall in level II becomes more direct and the paracolpium becomes shorter (Figs. 2 and 5). The connection of the anterior vaginal wall to the arcus tendineus fasciae of the pelvis forms a supportive layer that lies under the bladder and corresponds to the pubocervical fascia (Fig. 3). The posterior wall is attached to the superior fascia of the levator ani muscles and forms the rectovaginal fascia. Although the pubocervical fascia and rectovaginal fascia function as different layers, their continuity along the lateral margin of the vagina can be seen clearly (Fig. 5). In the lower regions of level II (in contradistinction to level I) the connective tissue of the paracolpium extends over both the anterior and posterior surfaces of the vagina in the midline.

The lateral attachments of the vagina to the arcus tendineus fasciae pelvis and superior fascia of the levator ani muscles in level II fix it firmly in place. Downward pressure on the anterior surface of the vagina toward the introitus is resisted by the anterior vaginal wall and its attachments to the arcus tendineus fasciae pelvis (pubocervical fascia). Upward pressure on the posterior surface of the vagina directed toward the introitus is resisted by the posterior vaginal wall and its attachments to the levator fascia (rectovaginal fascia). Unlike the vagina in level I, the vagina in this region cannot easily be moved in a cephalic direction.

Level III corresponds to the region of the vagina that extends from the introitus 2 to 3 cm above the hymenal ring and is fused with the structures that surround it. Unlike in the upper levels, there is no intervening connective tissue of the paracolpium that separates the vaginal wall from adjacent structures (Fig. 7). Anteriorly, the vagina fuses with the urethra and is embedded in the connective tissue of the perineal membrane (urogenital diaphragm). Laterally, it blends with the medial margins of the levator ani muscles. Posteriorly, it fuses with the perineal body. The vagina in this area has no

mobility separate from its adjacent structures. Displacement of the muscles, perineal body, or urethra carries the vagina with it. Lengthening of the levator ani in this area therefore opens the vaginal lumen but does not change the relationship between the vagina and the muscle. Clinically, this region is characterized by the visible contours of adjacent structures. The bulge of the medial border of the levator ani muscles, as well as that of the urethra, can be easily seen as the vaginal wall intimately covers their inner surfaces.

The three levels of vaginal support are continuous with one another and therefore are interdependent. For example, the upper border of level II depends for support on its connection to level I. In this way these portions are part of a continuum, although for the sake of convenience they have been described separately in this report.

Comment

In this study we found that it was not possible to evert the vaginal apex as long as the suspensory fibers in level I were intact. Therefore it would appear that the critical anatomic change in women with vaginal eversion after hysterectomy is failure of these suspensory fibers to hold the upper vagina in its normal position. In a woman who has previously had a hysterectomy, cystocele, or rectocele can develop as a result of problems in level II, but as long as the suspensory fibers of level I are intact, vaginal eversion does not occur. These fibers attach to the region of the vagina adjacent to the scar from the previous hysterectomy, so careful examination of patients with prolapse after hysterectomy should be directed toward determining whether the vaginal apex descends excessively with valsalva pressure or coughing to the level of the hymenal ring. As long as suspension of the vagina in level I is intact, failure of level II supports presents as cystocele or rectocele or both without eversion of the vagina. These cases can be managed with repair of the cystocele and rectocele. However, if the suspensory fibers in level I have failed, vaginal eversion persists immediately after colporrhaphy unless the vagina is resuspended.

The type of prolapse that is present after hysterectomy will depend on which levels of support have failed. Although usually thought of as a generalized process, genital prolapse occurs because of a combination of individual defects that affect localized areas.[11] Defective suspension of the vaginal apex (level I) with preservation of midvaginal support (level II) presents as a simple eversion of the upper vagina. It can be accompanied by downward prolapse of the peritoneum that is attached to the posterior vaginal wall, forming an enterocele, but as long as the level II supports are intact, there is no cystocele or rectocele. In these cases holding the vaginal apex at the level of the ischial spine while the woman strains relieves all visible prolapse, and suspension of the apex without other repair will be curative. This represented 33% of patients with vaginal eversion in our experience.[1]

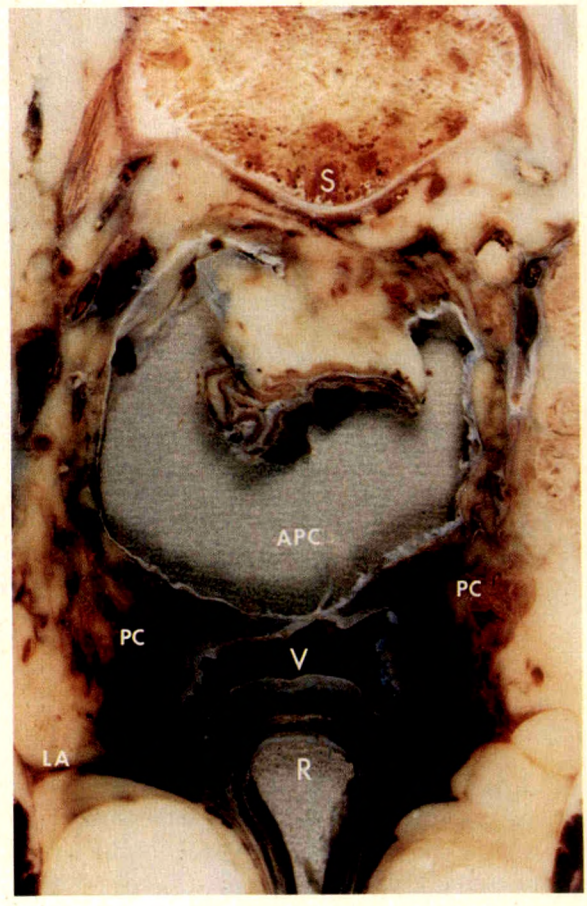

Fig. 4. Coronal section through upper vagina (level I) in 26-year-old cadaver that had previous hysterectomy, showing vertical orientation of paracolpium *(PC)* as it suspends vagina *(V)* above rectum *(R)* and levator ani *(LA)* muscles and below abdominopelvic cavity *(APC)*. *S*, Sacrum.

When the vaginal apex is no longer suspended and failure of the level II supports (pubocervical or rectovaginal fasciae) is also present, then vaginal eversion is associated with either a cystocele or a rectocele or both. This is referred to as complex vaginal eversion, whereby prolapse of the apex is accompanied by a cystocele or rectocele, and represents 67% of vaginal eversions.[1] Among these patients 7% have apical prolapse with cystocele and 30% have apical prolapse with rectocele, whereas 30% have both cystocele and rectocele along with vaginal eversion. In these individuals cystocele or rectocele or both are still present when the apex is held at its normal position during examination.

The attachments of the distal vagina to the medial margins of the levator ani muscles in level III are so dense that the lower portion of the vaginal wall always

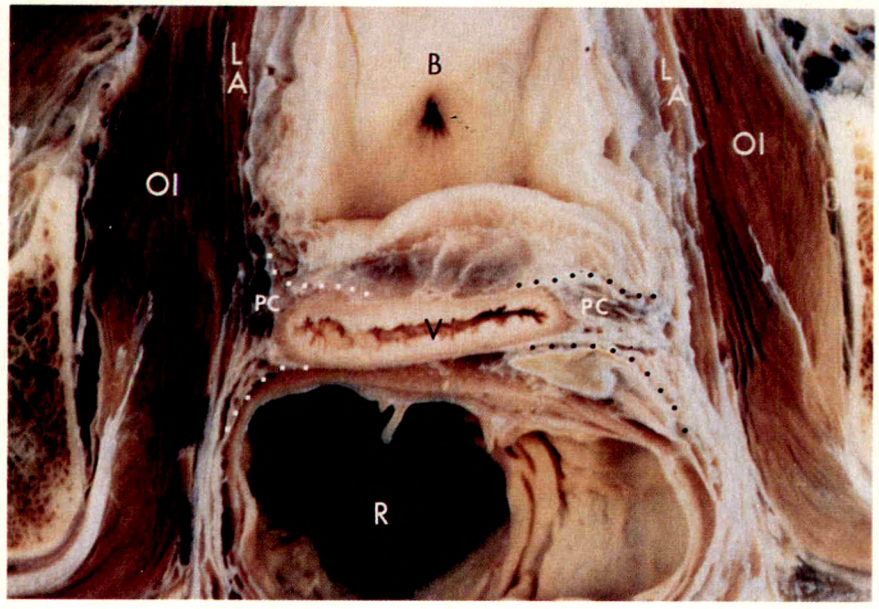

Fig. 5. Transverse whole-pelvis section of 14-year-old nulliparous cadaver. Asymmetry of specimen shows level I with long segment of paracolpium *(PC)* between vagina *(V)* and lateral pelvic wall on right *(black dot outline)*. remains attached in this region. The importance of this region has to do more with the ability of the levator ani muscles to keep the vagina closed than with the vagina's ability to remain attached to its surrounding structures. Certainly, damage to the perineal body and urethral supports in this region is important, but as yet this is poorly understood.

Considering the importance of the suspensory fibers in level I, how can this information be used to help prevent vaginal eversion after hysterectomy? In the normal individual the uterus and upper vagina are suspended by the continuous support offered by the parametrium (cardinal and uterosacral ligament complex) and the paracolpium in level I. This sheet of tissue is approximately 6 cm wide. During abdominal hysterectomy the cardinal ligaments and uterosacral ligaments are separated from the cervix, leaving only 2 to 3 cm of the paracolpium attached to the vagina. Furthermore, if transection of the paracolpium from the vagina is continued past the cervix for another 1 to 2 cm, then little of the level I fibers remains to support the vagina. This diminution of the suspensory fibers may well predispose patients to vaginal eversion later in life as the general deterioration in connective tissue occurs with age.

Anatomically, this area can be strengthened during hysterectomy not only by reattaching the cardinal and uterosacral ligaments to the vaginal apex but also by performing intrafascial hysterectomy techniques[12] that avoid detachment of any of the paracolpium from the vagina. This would allow the entire 6 cm of cardinal ligament and paracolpium to participate in support of the vaginal apex. The fact that vaginal eversion does not immediately follow detachment of the paracolpium from the vagina attests to the redundancy of support in normal women. However, women who have undergone hysterectomy and in whom parts of the suspensory apparatus were not reattached may be at increased risk for subsequent vaginal eversion because age weakens their supportive tissue. This could explain the fact that vaginal eversion develops in equal numbers of patients after abdominal and vaginal hysterectomy,[4] even though patients who undergo vaginal hysterectomy are more likely to have previously had prolapse. Improvement of vaginal suspension is consistent with traditional techniques that achieve elevation, in addition to obliterating the cul-de-sac,[13] and help to reestablish the normal depth and axis of the vagina.[14]

It is interesting that the difference in attachment of the vagina to the pelvic walls between levels I and II and level III parallels the different embryologic derivations of these regions. Levels I and II are derived from the müllerian ducts and have attachments to the lateral pelvic wall similar to those of the uterus and tubes. The lower portion of the vagina, the portion that is present in patients with müllerian agenesis (level III), comes from the urogenital sinus and does not have the paracolpium between it and adjacent structures.

It should be emphasized that this article discusses only one part of the multifaceted structure of the pelvic

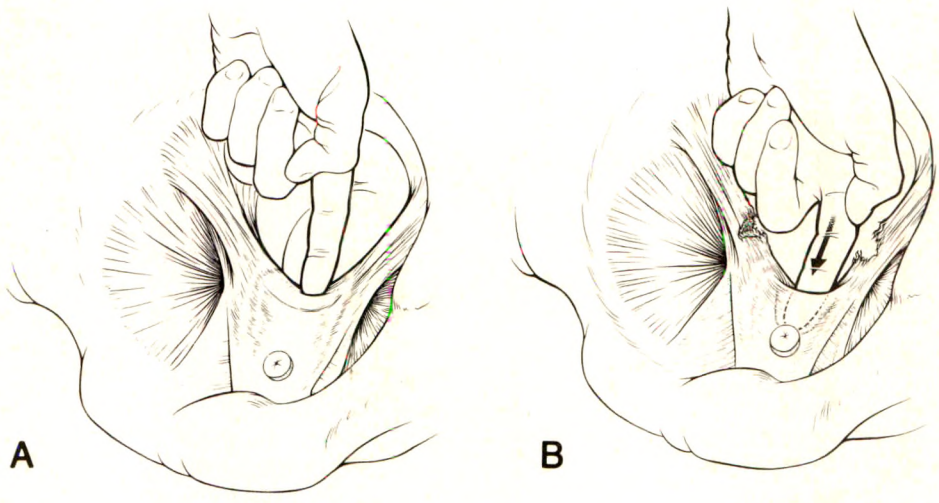

Fig. 6. A, When force is applied to vaginal apex, eversion of vagina is resisted by suspensory fibers of level I. **B,** Transecting fibers of level I permits eversion of vagina to occur.

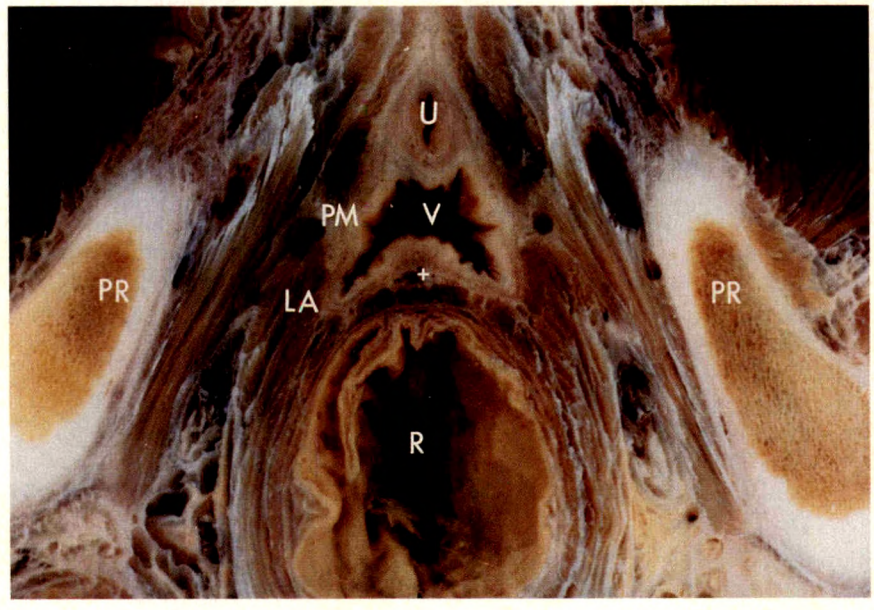

Fig. 7. Transverse section from cadaver shown in Fig. 5 at level III showing fusion of the vagina *(V)* to urethra *(U)*, perineal membrane *(PM)*, levator ani muscles *(LA)*, and top of perineal body (+). *PR*, Inferior pubic ramus; *R*, rectum.

floor. Many factors in addition to the connections of the vagina to the pelvic walls are crucial to pelvic support. The treatment of this one aspect of support in isolation does not imply that it is the only important element involved. Other factors such as damage to the levator ani muscles with resultant increased inclination of the levator plate[15] and alteration of the axis of the vagina[14] are also involved. Further objective studies comparing the anatomy of patients with prolapse with that of those with normal support will be necessary to clarify the relative importance of each of these factors in the development of prolapse. The current report, along with other anatomic investigations into the functional anatomy of the pelvic floor, should prove helpful in directing such studies.

Discussion

Dr. Stephen H. Cruikshank, Minneapolis, Minnesota. Dr. DeLancey has presented an excellent anatomic description of the three known levels of vaginal support. He has pioneered a single study that microscopically delineates these different levels of support and the sequelae to each level, should a defect occur. The Abstract, Introduction, Material and Methods, and Results sections of his manuscript clearly fit the style of a well-written scientific article; however, I would like the audience and readership to concentrate on the Comment section and Dr. DeLancey's conclusions.

In his study Dr. DeLancey microscopically documented what we have studied, discussed, and clinically concluded no less than four times over the past 5 years at the Central Association meetings. He proved it anatomically using cadavers. He states that his work supports the claims others have made clinically. I would offer here a word of caution. I offer my support to this study, which is excellent in experimental design and concept. I believe it has gotten to the basis of our clinical practice, which is well documented in the literature.[1-4] However, we should never rely entirely on the results of one study; it is hoped that there will be more studies, reproducing these results of Dr. DeLancey and others.

He has examined a group of cadavers, which do not have the same variables as living patients undergoing procedures (we must take into consideration the style of a surgeon, operator knowledge of anatomy, tissue structure of each patient, underlying diseases, etc.).

Dr. DeLancey has eliminated these variables. The controversy that Dr. DeLancey alludes to in the Comment section is indeed created by these factors. Dr. DeLancey claims that the immersion method eliminates distortion, but he has not compared results with this method to those of a living clinical control group.

Specifically, I would like to address three conclusions that stood out in his discussion. He stated: (1) ". . . this area can be strengthened during hysterectomy not only by reattaching the cardinal and uterosacral ligaments to the vaginal apex but also by performing intrafascial techniques. . . ." (2) ". . . women . . . in whom parts of the suspensory apparatus were not reattached may be at risk for subsequent vaginal eversion." (3) "Improvement of vaginal suspension is consistent with traditional techniques that achieve elevation, in addition to obliterating the cul-de-sac, and help to reestablish the normal depth and axis of the vagina." Although Dr. DeLancey concludes these points clearly, they are not new to our profession. However, I am particularly pleased to draw attention to these statements for these conclusions are the same ones that followed studies also presented here in the past.[2-4]

I have three questions that I would like Dr. DeLancey to answer: (1) Clinically, in the office and/or operating room, do you examine patients with the uterus in situ to decide which patients are at possible risk for future vaginal eversion, and how? (2) If you find evidence clinically that a patient has partial defects of the vaginal apex with the uterus in situ, to what extent will you go in your repair to prevent posthysterectomy prolapse? (3) In those patients found to have moderate to severe vaginal eversion with an in situ uterus, what prophylactic methods (prophylactic means to prevent, to ward off) would you use to fully correct the defect of level I suspension?

Dr. DeLancey, I congratulate you. You are a pioneer, truly focused. Aside from the above-mentioned points, you have pioneered a study that has proved microscopically the clinical anatomy of an infrequent, yet tragic (for the patient) complication of hysterectomy—vaginal vault eversion.

Dr. G. Rodney Meeks, Jackson, Mississippi. I congratulate Dr. DeLancey on his excellent article. He has devoted a significant portion of his career to helping us understand the anatomy and function of pelvic floor support. Dr. DeLancey has a unique opportunity to evaluate histologic and whole-pelvic cross sections. Because of constraints imposed by limited availability of

cadavers, most of us cannot reproduce such basic studies. This article makes a very complex subject understandable. This is accomplished by clear thinking about the subject, concisely written descriptions of the anatomy, thoughtful conclusions, and the use of excellent figures.

The study design is one of simple observation, a technique that is common when surgical and/or anatomic questions are evaluated. No attempt has been made to quantify the degree of vaginal eversion in the specimens nor has the force required to produce prolapse of the vagina been discussed. The question, "How many fibers of the paracolpium can be damaged or lost before prolapse occurs?" has not been addressed. The specimens were studied in an upright position, which may remove some of the potential artifacts.

Describing three levels of vaginal support gives to clinicians a mechanism to explain pelvic floor defects. Furthermore, the information may provide a rationale for selecting a surgical repair technique. It may help to identify patients in whom vaginal vault suspension is appropriate. Could it vindicate Dr. Cruikshank's stance[1] of "prophylactic suspension"? Whereas this presentation is accurate on the basis of my clinical experience, could the conclusions be biased? That is, could the anatomic descriptions in this article reflect what is used clinically and thus justify a specific surgical approach without proving that these anatomic structures are responsible for support? Dr. DeLancey has addressed the question that he proposed in regard to what differentiates women with vaginal prolapse from women with cystocele, rectocele, and enterocele alone. The answer is loss or damage of supporting structures. I remain confused in regard to ways to lessen the likelihood of prolapse after hysterectomy. He has not provided a "how to" for surgeons. Several specific questions may clarify these points: (1) Can this description of vaginal support help clinicians to recognize patients at risk for prolapse? (2) Do partial defects occur? If so, to what extent should one go to identify these defects? (3) What measures can be taken to prevent pelvic floor defects after hysterectomy? (4) Does leaving the vaginal cuff open at the time of hysterectomy have any effect on the risk of vaginal prolapse? (5) Does a closure technique that reapproximates the cardinal and uterosacral complex to the midline have any effect on the risk of vaginal prolapse? (6) If the fascia surrounding the vagina and the cardinal-uterosacral complex are important to support the cuff, would a subtotal hysterectomy, leaving the cervix and its attachments intact, minimize surgical damage and thus reduce the likelihood of prolapse? (7) Does cul-de-sac obliteration have any role? (8) Does the hiatus levator ani have any impact at all on level I and II defects?

1. Cruikshank SH. Sacrospinous fixation—should this be performed at the time of vaginal hysterectomy? Am J Obstet Gynecol 1991;164:1072-6.

Dr. Christopher J. Jolles, Salt Lake City, Utah. I applaud Dr. DeLancey and his efforts to understand the anatomic principles relating to the operations that we perform, for indeed we are surgeons and are responsible for understanding anatomy and the physical basis of what we do.

During a radical hysterectomy, we dissect the uterosacral ligaments from their origin in the posterior aspect of the cervix down to the window joining the pararectal and rectovaginal space. The entire ligament is clamped and divided, and no effort is made to reattach remnants of this ligament to the vaginal vault.

Frankly, I have never seen a significant vault prolapse in a patient who has undergone a radical hysterectomy. Therefore I wonder what impact this factor has on our understanding of the necessity of paracolpial support to prevent vault prolapse.

Dr. Lane J. Mercer, Chicago, Illinois. Dr. DeLancey, I also want to congratulate you for your fine work and article. I want to point out, perhaps because I am a bit of a hometowner, that Dr. Curtis at Northwestern University described something called a pararectal fascia, which also describes the tissue you are calling the paracolpium. He later developed a suspension of the vaginal apex after vaginal hysterectomy by use of this tissue, which has proved successful.

Long-term experiences have shown that this suspension at the conclusion of vaginal hysterectomy provides results at least as good as those we now attribute to the sacrospinous ligament suspension. I would appreciate your comments about that.

Second, using your description of various levels of vaginal defects, we are seeing posthysterectomy vaginal eversion treated all too often with a level I correction, that is, a sacrospinous ligament suspension, and the level II defect addressed with an anteroposterior colporrhaphy, which does little except to decrease or tighten the caliber of the vagina. It does nothing to suspend it. I would appreciate your comments about how you would handle such patients on the basis of your anatomic findings.

Dr. Kenneth Webster, Cleveland, Ohio. I would like to reiterate Dr. Jolles' comments in that, as gynecologic oncologists, we have a living role model for each case of pelvic dissection. Once again, if the entire uterosacral ligament is removed along with the uterus and upper vagina, as well as the cardinal ligament, there is nothing to resew to the apex of the vagina. In 21 years of postoperative experience, I have never seen a vault prolapse in a patient undergoing radical hysterectomy.

Dr. Suzanne R. Trupin, Champaign, Illinois. I was just curious about whether this patient population was premenopausal or postmenopausal and if the author could comment on whether the pelvic support ligaments are significantly changed in these populations.

Dr. Maurice J. Webb, Rochester, Minnesota. Congratulations on an elegant study. The aspect I would question is that you are concentrating on the lateral supports of the vagina. You did mention that the vagina

incorporated pubocervical and rectovaginal fascia. Would you comment on the thought that possibly some of the weakness that develops in prolapse is not in the lateral supports but is due to the central weakness of this fascia, which allows the protrusion to occur?

PRESIDENT YOUNGBLOOD, Kansas City, Missouri. I had the privilege of reviewing this article. You made a clear statement that intrafascial hysterectomy would seem to be the way to go as far as technique is concerned. You didn't mention that today, and I wonder if you would comment on that.

DR. DELANCEY (Closing). I thank both Dr. Cruikshank and Dr. Meeks for their thoughtful and probing discussion. They have raised several very important issues. I will go through them in the order in which they were presented.

I would agree with Dr. Cruikshank's comment that it is very difficult to know about the distortions that occur in an anatomic specimen when compared with a living individual. The most profound one comes from the lack of contractility of the levator ani muscle, and that is a limitation in all anatomic studies and at the present time cannot be overcome. However, if you keep that in mind while dissecting and don't overinterpret what you see, then it is possible to look at the connective tissue (which tends to change relatively little after death) with some accuracy. The potential distortions are important, and we must keep them in mind when interpreting the results of these anatomic studies.

We actually did compare the spatial relationships in cadavers fixed by immersion with measurements that are available from living individuals. As mentioned in the manuscript, there is a book by Dickinson that was published in the 1950s that contains measurements of pelvic anatomy in living women, and we were able to document the fact that the immersion technique resulted in the same topography that was found in the living individual. Certainly, in the unfixed cadavers there are no similar data with which to compare.

The next issue that Dr. Cruikshank raised, and I think it is a critical one for us to consider, is the fact that there is a large difference between what I present as anatomic findings and what is presented in a discussion of clinical applications of these findings, the latter being a largely philosophic discussion.

I have no specific data to present concerning the suspension of the vagina at the time of abdominal or vaginal hysterectomy. The discussion of this issue deserves the kind of careful study that Dr. Cruikshank has done in his articles in which he carried out follow-up of patients after various suspension techniques. The wisest course for us to follow is to look at the anatomy of vaginal support for an approach to supporting the vaginal apex but to actually depend on clinical follow-up studies of different techniques to gain data on the success of those different suspension techniques.

Dr. Cruikshank also asked about the office evaluation of a patient to detect the degree of apical prolapse that is present with or without the uterus in situ. We do this in both the supine and the standing position. The hymenal ring is a reliable reference point, and you can simply measure the distance of the scar at the vaginal apex relative to the hymenal ring, either above it or below it, to document the degree of apical prolapse that is present once the prolapse has maximally developed.

He also asked about partial defects in the support of the vaginal apex, which is a very important issue. The status of vaginal support is not a yes-or-no question, it's a "how much" question. It is not, is the vagina prolapsed? It is, how far down is the apex relative to the position that it should normally be in (which is approximately 4 to 6 cm above the hymenal ring in the resting individual).

Our quantitative studies on cervical descent[1] revealed that the lateral margin of the cervix can be pulled to the level of the hymenal ring in the normal, anesthetized, multiparous woman. In interpreting the normal support of the vaginal apex under traction, we need to gather some data about this by taking asymptomatic patients who have previously undergone hysterectomy and ascertaining the location of the vaginal apex. I think that Dr. Cruikshank is right, that there are partial defects that occur. Sometimes the vaginal apex is well supported; other times it's obviously everted, and then there's a large group of patients who are in the middle with varying degrees of descent.

Dr. Cruikshank also raises the issue of patients who have moderate to severe uterovaginal prolapse. In these individuals tenaculum traction may cause the cervix to protrude, for example, 4 cm below the hymenal ring. The vagina is attached to the cervix, and he points out that the vagina prolapses as well.

There are a number of other techniques that have been proposed to resuspend the vagina in these patients, which are performed in conjunction with vaginal hysterectomy. At present one can only speculate on the importance of any one of these techniques because there aren't sufficient data to be able to discriminate between the long-term outcomes of various resuspension techniques.

Dr. Meeks has asked if we can identify the patients who are at risk for prolapse. This could mean one of two groups: (1) the patients who have true prolapse that is undetected or (2) those in whom prolapse may develop in the future but who are normal now. I would comment that at present, because prolapse is a non-life-threatening condition and many women have asymptomatic relaxation, we should focus not on prognosis except for the purposes of scientific studies but rather on the important diagnostic aspect of detecting prolapse when it is present. It is important to know where the apex of the vagina is in the woman who has defective support after hysterectomy. If an inadequate preoperative examination is performed and the patient isn't straining forcefully enough, a vaginal eversion that is present will be undetected. Anterior and posterior colporrhaphy performed under the presumption that this is a simple cystocele and rectocele will fail to correct

the prolapse unless something is done to resuspend the vagina at that time. I would emphasize this as a diagnostic and not prognostic issue.

Dr. Meeks also raised the question of partial defects that we've already addressed and then again asked about the management of the vaginal cuff at the time of hysterectomy, specifically raising the issue of whether leaving the cuff open adds to support of the vagina, assuming that it will become adherent to the structures that surround it. This mechanism for support has been discussed for many years. It seems to me anatomically implausible because the ligaments retract fairly quickly after you release them and, unless they are reattached to the cuff, cannot be expected to seal to it.

Tying the ligaments together in the midline to resuspend the vaginal apex is a technique that comes from the concept that the suspensory ligaments are transverse, as implied by the term *transverse cervical ligaments*. The concept that the ligaments run horizontally from the pelvic sidewall inwardly toward the cervix is a misapprehension that comes from looking at cross-sectional material. When we made three-dimensional reconstructions of the anatomy in this area, it was obvious that the fibers of the cardinal ligaments are vertical in the standing individual. So it is illogical to pull things together in the midline because normally those ligaments do not come to the midline but attach vertically to the lateral margins of the vagina and the cervix.

A supracervical hysterectomy, by preserving the attachments of the ligaments to the genital tract, might help to maintain support of the genital tract, but I think the significant and continuing problems with cervical carcinoma would outweigh the considerations about genital prolapse, especially since we have relatively good treatment for genital prolapse and less satisfactory treatment for malignant disease of the cervix.

A cul-de-sac obliteration remains an important part of our surgical management in these individuals, although we have few specific data concerning that. Our approach is to focus on the fibrous attachments, and we have not considered the cul-de-sac separately.

The hiatus of the levator ani muscle is of importance, and the function of the levator ani muscle itself is also critical. I believe that the levator ani muscles are more important than the fibrous connections of the vagina to the pelvic sidewall. We are just beginning to gather data on this condition. It is something that Halban and Tandler[4], who did the most extensive studies of the pathophysiologic characteristics of genital prolapse, maintain very forcefully throughout their work, and I am starting to believe that, in fact, the levator ani muscle is the primary structure responsible for normal support. Today I have focused on the fibrous supports to define them, but I believe that over the course of the next several years we will begin to better appreciate the importance of the levator muscles to support.

Dr. Jolles raised the issue of the detachment of paracolpium from the vagina during radical hysterectomy and asks why this doesn't lead to prolapse. It is also true that at the same time an upper vaginectomy is performed. The portion of the vagina that depends on level I suspension is removed along with the radical hysterectomy specimen as an upper vaginectomy; that portion of the vagina that would be unsupported after detachment of these ligaments is therefore no longer there to prolapse. This explains the fact that there is no vaginal prolapse afterward.

The other issue in these patients concerns the fact that the levator ani muscle probably functions normally in patients with cervical cancer, and so there's much less downward force on the fibrous connective tissue because the pelvic floor remains closed through normal muscular activity. Further studies of individuals in whom the detachment occurs but the upper vagina is not excised might be a very good way for us to test some of these issues.

Dr. Mercer brought up the concept of the pararectal fascia as a supportive element. When you become interested in the endopelvic fascia as I have, it is inevitable that you collect a long list of terms for the endopelvic fascia. There are probably 70 different names that have been applied to this one body of connective tissue, and pararectal fascia is one of the terms that occurs commonly.

The endopelvic fascia is a continuous tissue that has various regions. When someone studies it and becomes interested in a particular region, they are naturally drawn toward the idea of inventing their own name for it. The paracolpium actually is an established anatomic term that has been more popular in the German anatomic studies. The pararectal fascia is the posterior extension of the connections of the vagina, and there are a number of reports using that fascia which overlies the iliococcygeus muscle for resuspension. That technique does seem to be effective.

The second question that Dr. Mercer raised has to do with separate consideration of level I and level II at the time of treatment of vaginal eversion. I would agree with Dr. Mercer that the problems of resuspending the vagina (level I) are ones that are successfully accomplished with several techniques, including sacrocolpopexy, sacrospinous ligament suspension, and some other modifications of those.

The current problem is not with achieving good apical support. It's the cystocele (level II) that develops afterward, as Shull et al.[2] described. The concept that a cystocele develops because the pubocervical fascia stretched is an entirely unproved concept. Goff,[3] in the 1940s, examined the then-current hypothesis that it was the thinning of the pubocervical fascia that was responsible for cystourethrocele. He found, when he looked at the pubocervical fascia in individuals with cystocele-urethrocele, that it was actually thicker than in the normal individual not thinner as most people suppose.

This very important question raises the issue of the scientific study of pelvic floor function and pelvic floor support. With the armamentarium of imaging tech-

niques and the sophisticated physiologic measuring instruments available we can begin to get out of the arena of opinion about these issues and start to collect data that can answer some of these important clinical questions that have been raised today.

I think that it was Dr. Trupin who mentioned the important question of premenopausal and postmenopausal changes. I didn't have time to detail the ages of our cadavers, although they are included in the original manuscript. The age range was from 7 months to 104 years. The mean age of the cadavers was the mid-50s.

It is certainly possible to see changes that occur in the connective tissue with age. It becomes much less robust and much more fragile. There didn't seem to be precipitate change with the menopause, but there did seem to be quite a dramatic change over the course of examining both young and old cadavers. That's another area that we will be able to collect data on over the course of the next 5 or 10 years.

Receiver-operator characteristic, efficiency analysis, and predictive value of serum progesterone concentration as a test for abnormal gestations

Bryan D. Cowan, MD, David T. Vandermolen, MD, Cecil A. Long, MD, and Neil S. Whitworth, PhD

Jackson, Mississippi

OBJECTIVE: Our objective was to determine if a disciminatory progesterone concentration could be established that confidently predicted abnormal early gestations.

STUDY DESIGN: We analyzed differences in progesterone concentrations between normal (n = 40) and abnormal (n = 34) pregnancies during the first 49 days of gestation. The receiver-operator characteristic curve, test efficiency, and predictive value of serum progesterone to discriminate between an abnormal and normal first-trimester gestation were calculated for progesterone concentrations between 5 and 25 ng/ml.

RESULTS: Receiver-operator characteristic curve analysis indicated that the best discriminatory progesterone concentration was 10 ng/ml. Test efficiency was maximum between serum progesterone concentration of 9 to 14 ng/ml (80%). When progesterone was <10 ng/ml, the predictive value of the abnormal test result was >90%.

CONCLUSION: Receiver-operator characteristic analysis, test efficiency, and the predictive value of an abnormal test result suggest that the best progesterone cut off point that predicts abnormal early pregnancies is 10 ng/ml. (Am J Obstet Gynecol 1992;166:1729-37.)

Key words: Receiver-operator characteristic, efficiency analysis, progesterone, abnormal gestation

Low serum progesterone concentrations are associated with abnormal (abortive and ectopic) gestations. However, the specific concentration of serum progesterone that represents the best discriminator of an abnormal gestation is unknown. Johansson[1] was the first to demonstrate that abnormal early gestations had progesterone concentrations lower than those of viable intrauterine pregnancies. More recent studies have expanded and quantitated these observations. Matthews et al.[2] and Yeko et al.[3] reported that serum progesterone concentrations of ectopic pregnancies were <15 ng/ml and did not overlap with the distribution of concentrations of normal intrauterine pregnancies. Furthermore, few intrauterine abortions had progesterone concentrations ≥15 ng/ml. Hubinot et al.[4] reported less uniform results, noting that 11% (64/578) of normal gestations had a concentration <15 ng/ml. Stovall et al.[5] screened 582 emergency room admissions for early pregnancy complications with a single serum progesterone measurement and observed that 13 of 67 ectopic pregnancies (19%) had a concentration ≥15 ng/ml, whereas 11% of the normal pregnancy population had a concentration <15 ng/ml. Thus the optimal discriminatory progesterone concentration that can diagnose abnormal pregnancies is not well established. As a result, its potential accuracy in predicting abnormal first-trimester gestations is unclear.

For this reason we tested the efficacy of a wide range of progesterone values in discriminating between normal and abnormal pregnancies during the first 49 days of gestation. These data were analyzed by statistical methods that evaluate the performance of the test (predictive value and test efficiency) and the detection rates of conditions within the study population (sensitivity). In this way, decisions concerning the ability of serum progesterone measurements to detect abnormal pregnancies can be based on the performance of the test rather than an arbitrary assignment of cut-off points.

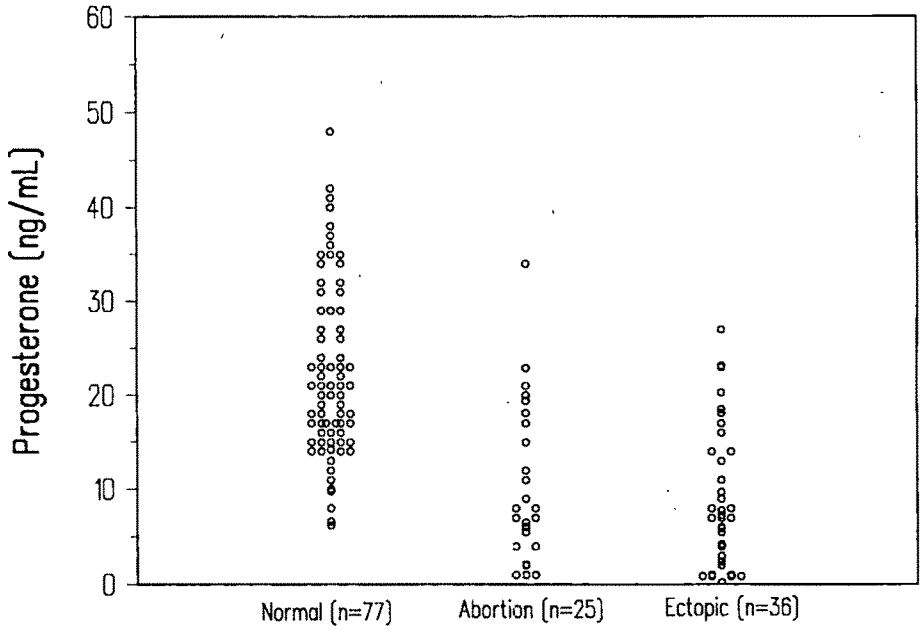

Fig. 1. Distribution of progesterone concentrations in women with normal, abortive, and ectopic pregnancies during first 49 days of pregnancy.

Table I. Summary of number of patients, observations, and mean progesterone concentration by condition of first-trimester gestations

Condition	*No. of patients*	*Observations*	*Progesterone (ng/ml)*	*SEM*
Normal	40	77	24.1	1.5
Aborted	16	25	10.5	1.7
Ectopic	18	36	9.0	1.2

between 28 and 49 days from last menstrual period (LMP) who were judged to be at risk for ectopic pregnancy had serum progesterone measurements one to three times per week until diagnosis. Risk was assigned on the basis of previous history of infertility, tubal or abdominal surgery, or previous ectopic pregnancy. Serum progesterone concentrations were determined by radioimmunoassay with a commercially available kit (Diagnostic Products Corporation, Los Angeles, Calif.). The intraassay and interassay coefficient of variation was 8% and 10%, respectively. All patients conceived spontaneously. Patients were classified into three groups on the basis of the final diagnosis: group 1, normal pregnancy (n = 40); group 2, abortive intrauterine pregnancy (n = 16); and group 3, ectopic (tubal) pregnancy (n = 18). Twenty-one concentrations of progesterone (5 to 25 ng/ml at 1 ng/ml increments) were used to test critical levels that best determined normal and abnormal results.

Statistics. The capacity of a given progesterone level to discriminate between abnormal (ectopic and abortive) and normal pregnancies was determined with 2×2 contingency tables to calculate the predictive value, test efficiency, sensitivity, and specificity at specific progesterone concentrations.[6] The contingency table had the following structure:

	Abnormal condition	*Normal condition*
Abnormal test	a	c
Normal test	b	d

The abnormal test result is the predictive value of the test to determine an abnormal condition when progesterone is below the tested concentration $(a/a + c)$, and the normal test result is the probability of a normal condition when progesterone is above the tested concentration $(d/d + b)$. The normal and abnormal test result were individually correlated with serum progesterone. The test efficiency is the proportion of patients correctly assigned as either normal or abnormal $(a + d/a + b + c + d)$. Test efficiency was also correlated with progesterone concentrations. A receiver-operator characteristic curve was used to determine the best discriminatory progesterone concentration by plot-

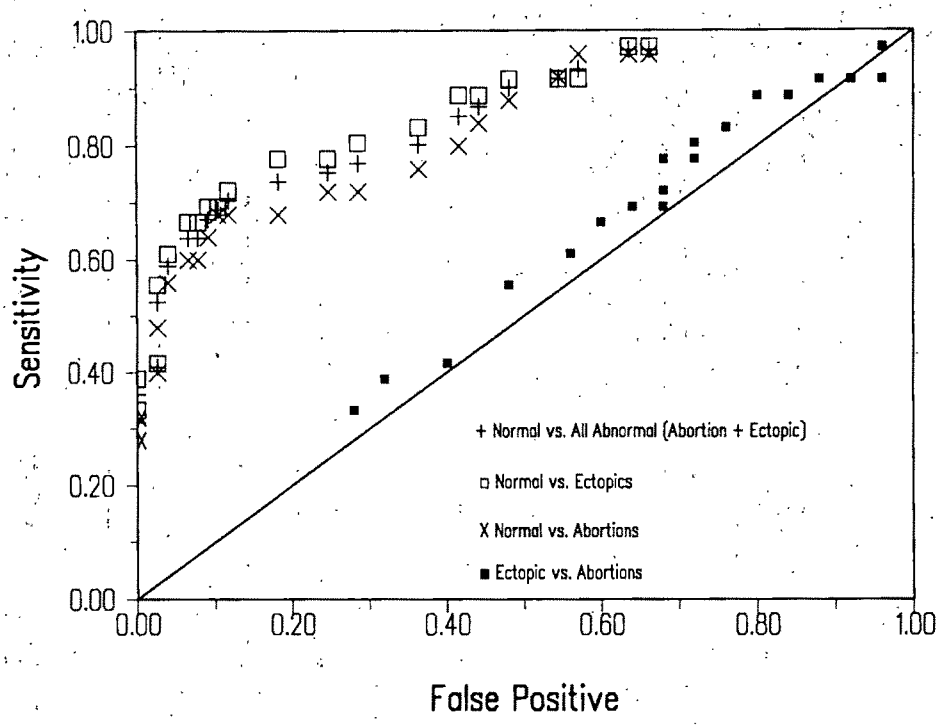

Fig. 2. Receiver-operator characteristic curve. This analysis correlates sensitivity of test with false-positive rate (1 − specificity) for each progesterone concentration tested. Analysis was performed comparing normal pregnancies against all abnormal pregnancies (+), intrauterine abortions (×), and ectopic pregnancies *(open box)*. Additionally, receiver-operator characteristic curve of ectopic pregnancies compared with abortions is plotted *(block)*. *Diagonal line* drawn from 0.00 to 1.00 represents "worst" curve.

ting the sensitivity $(a/a + b)$ of the test at each progesterone level against the percent of normal subjects incorrectly classified as abnormal (false positive = 1 − specificity $(d/d + c)$). The benefit of predictive value and test efficiency calculations are their ability to estimate the performance of the test. The value of the receiver-operator characteristic analysis lies in its ability to provide a clear computational model of the test over the full range of discriminatory progesterone concentrations and estimate the best or discriminatory cutoff for the test. The mean serum progesterone concentrations of each group were compared with a *t* test.

Results

Table I summarizes the number of patients, the number of serum progesterone values, and the mean serum progesterone concentration in each diagnostic group. The average progesterone concentration in women with a normal gestation was 24.1 ± 1.5, intrauterine abortion was 10.5 ± 1.7, and ectopic pregnancy was 9.0 ± 1.2 ng/ml (mean ± SEM). The mean progesterone concentration in normal gestations was significantly higher ($p < 0.001$) than the progesterone of either ectopic or abnormal intrauterine gestations. The mean progesterone concentration in women with abnormal intrauterine gestations was not significantly different ($p = 0.268$) than that in women with a tubal pregnancy. These data are graphically represented in Fig. 1.

Fig. 2 compares the receiver-operator characteristics curves for normal pregnancies against abnormal gestations (abortion and ectopic), abortions only, and abortion versus ectopic pregnancy at 21 progesterone concentrations. This analysis demonstrates a favorable improvement in the true-positive rate (sensitivity) and minimal inclusion of false-positive results when progesterone concentrations are between 5 and 10 ng/ml for normal pregnancy comparisons. When the discriminatory progesterone is >10 ng/ml, the curve becomes flat. This indicates that a discriminatory progesterone >10 ng/ml provides little improvement for the detection of true-positive conditions, but only includes more false-negative results. Additionally, the receiver-operator characteristics curve for abortions and ectopic pregnancies *(solid block)* indicates that these conditions are indistinguishable from one another on the basis of progesterone testing. The slope of the linear regression is 1.05, and the correlation coefficient is 0.986. A receiver-operator characteristics curve that is parallel to

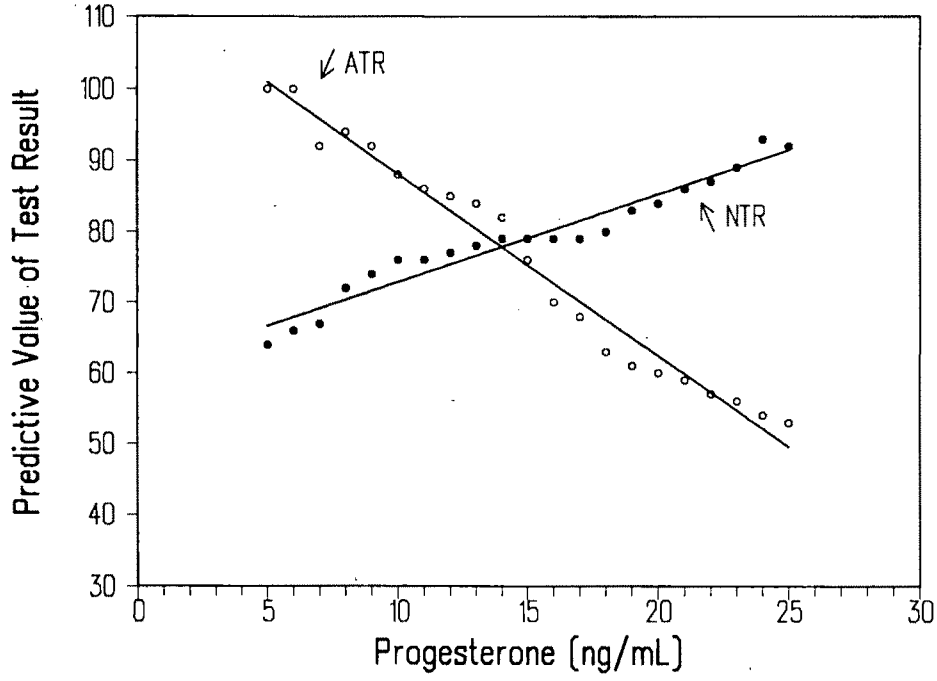

Fig. 3. Predictive value of abnormal test result *(ATR)* and normal test result *(NTR)* compared with discriminatory serum progesterone concentration in women with normal or abnormal gestations.

The normal test result represents the ability of the test (progesterone concentration) to predict the normal condition when progesterone is above the cutoff level. The abnormal test result represents the ability of the test to predict the abnormal condition when progesterone is below the cutoff level. Calculations were performed at 21 progesterone concentrations (5 to 25 ng/ml) and normal pregnancies were compared with abnormal pregnancies (aborted and ectopic).

a diagonal line drawn from 0,0 to 1,1 represents a poor (worst) test, having no ability to detect either condition.

Because abortions could not be distinguished from ectopic pregnancies, our analysis of predictive value and test efficiency focused on testing for normal pregnancies compared with abnormal conditions (abortion and ectopic). Table II summarizes the normal and abnormal test result for normal gestations compared with abnormal gestations for progesterone concentrations betweeen 5 and 25 ng/ml. The abnormal test result for normal versus abnormal pregnancies ranged from 53% to 100% over the range of serum progesterone con-

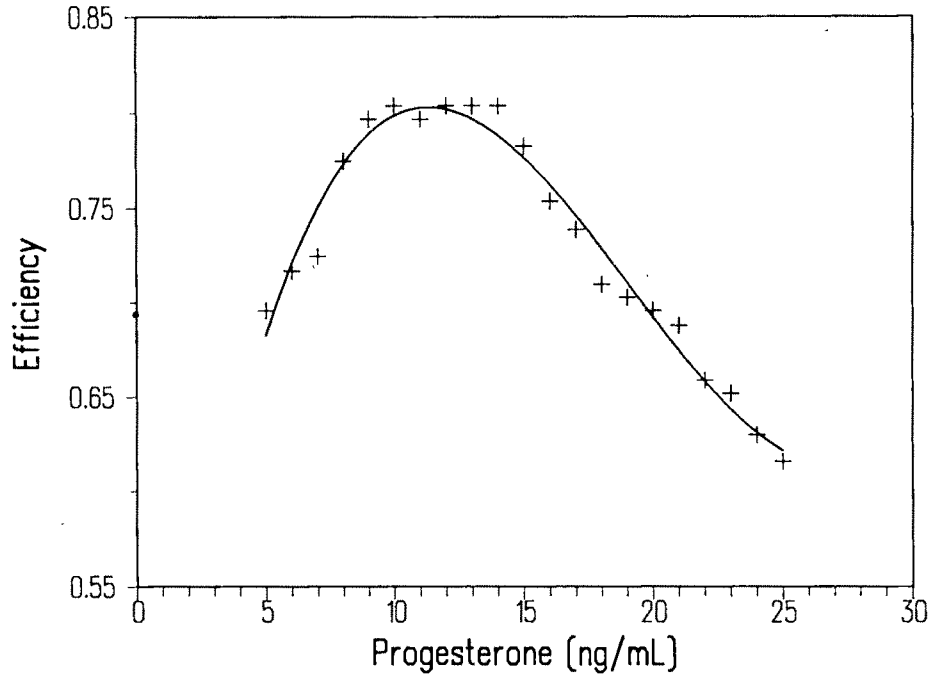

Fig. 4. Correlation of test efficiency (proportion of cases correctly classified either abnormal or normal) with serum progesterone. Second-order polynomial describes these data ($y = 0.353 + 0.093x - 0.006x^2$, $r = 0.986$).

centrations tested. The progesterone concentration tested was negatively correlated with the abnormal test result (Fig. 3). The linear regression of the abnormal test result for abnormal gestations demonstrated a significant negative correlation with increasing progesterone concentrations ($r = -0.988$).

The normal test result of the progesterone discriminatory test is also summarized in Table II. Just like the abnormal test result, these calculations compared normal versus abnormal gestations at 21 progesterone concentrations. The normal test result was a poor predictor of a normal pregnancy and was not ≥80% until the progesterone concentration was ≥18 ng/ml. Fig. 3 shows the correlation between the normal test result derived from these calculations with progesterone concentrations. It was positively correlated with increasing progesterone concentrations ($r = 0.972$).

Fig. 4 correlates the test efficiency for simultaneous detection of normal and abnormal gestations with progesterone concentrations. Peak efficiency occurred when progesterone concentrations ranged from 9 to 14 ng/ml. The test efficiency ranged from 79.7% to 80.4% in this range of progesterone.

Comment

Human chorionic gonadotropin (hCG)[8-13] and ultrasonographic monitoring[14] of early pregnancy usually require several days of observation before a confident diagnosis can be determined. Furthermore, ectopic gestations may not produce sufficient quantities of hCG to raise the serum concentration of hCG to the discriminatory ultrasonographic range before rupture or tubal injury occurs. Because of these limitations, other rapid monitors or early gestational normalcy have been sought.

Progesterone monitoring of early gestations has been studied as an alternative to serial hCG monitoring by several authors.[2-5] Only a single measurement is required compared with the serial observations required for hCG concentrations. Unfortunately, most reports describing the use of progesterone have established cutoff points empirically and have not sought the "best test" of their analysis. Statistical tools that allow informed decisions concerning the best test include the receiver-operator characteristic curve, the predictive value of the test, and test efficiency.[6] All offer simple computational solutions to the problem faced by physicians who must determine the best test for a clinical condition. They allow us to maximize the detection of the condition of interest and minimize erroneous classifications, and they are ideally suited for the problem of the best test analysis here.

The advantage of the receiver-operator characteristic curve is its ability to determine the best test to diagnose a condition. Fig. 2 illustrates two important points concerning the progesterone cutoff points. First, as the progesterone concentration increases, both the sensitivity and false-positive rate increase. Second, any progesterone concentration can be selected as a discriminatory cutoff, but the best cutoff is that associated with highest sensitivity and lowest false-positive rate. In our data, receiver-operator characteristic curve analysis in-

dicated that a progesterone concentration <10 ng/ml is the optimal discriminatory test. False-positive rates are <5% (0% to 3.9%) at this concentration, and the maximum sensitivity is 59%. Higher sensitivities can be obtained at higher progesterone concentrations, but the false-positive rate increases dramatically as well. Additionally, the receiver-operator characteristic curve demonstrates that progesterone monitoring of early gestations cannot distinguish between ectopic pregnancies and abortions.

At the derived best cutoff point (10 ng/ml), the predictive value, rather than the sensitivity, is the best indicator of how well the test will perform. The abnormal test result of abnormal gestations was >90% (92% to 100%) when the progesterone level was <10 ng/ml. This suggests that when the discriminatory progesterone concentration is 10 ng/ml, this test would correctly identify at least 90% of all abnormal gestations. Unfortunately, the normal test result is unable to determine gestational normalcy. The probability of a normal gestation is not >80% until the progesterone level is ≥18 ng/ml. Thus caution must be exercised by the clinician to not overinterpret the significance of a high serum progesterone concentration. Further analysis of the ability of the normal test result to exclude ectopic pregnancies and detect normal gestations is required.

Test efficiency analysis indicated that simultaneous detection of abnormal and normal conditions was maximal when the progesterone cutoff ranged from 9 to 14 ng/ml. This reassures us that the cutoff point of 10 ng/ml derived for the receiver-operator characteristic provides high predictive value and maximum test efficiency.

Potential biases of this study may affect our analysis. First, the optimal progesterone cutoff point may vary as a function of the specific reagents or assay used to determine serum progesterone concentrations. Second, our study incorporated multiple progesterone measurements on each patient. The average number of observations for each patient in the three groups was not significantly different (normal 1.8, abortion 1.6, ectopic 2.0, $p = 0.199$). This potential bias could be eliminated by increasing the number of patients and using only one data point per patient. Another potential bias is the relatively high proportion of ectopic pregnancies identified in this study group. We purposely excluded abortion and ectopic patients who had symptoms or an obvious diagnosis. Such patients were managed on an emergency basis without the need to estimate their risk. Additionally, many patients in our practice were excluded because they conceived after follicular stimulation with human menopausal gonadotropins or clomiphene citrate. These preparations significantly increase progesterone concentrations in all three groups (data not shown).

We believe that our analysis is representative of women who conceive spontaneously. It is the first attempt to determine the "best" discriminatory progesterone concentration on the basis of statistical modeling of the test. As our series enlarges and as additional tests are derived, these can be measured against our preliminary data. In this fashion informed decisions concerning the efficacy of new tests and the best cutoff point for progesterone can be compared.

Discussion

DR. THOMAS G. STOVALL, Memphis, Tennessee. Serial quantitative hCG titers in samples taken 48 hours apart have long been the standard endocrinologic

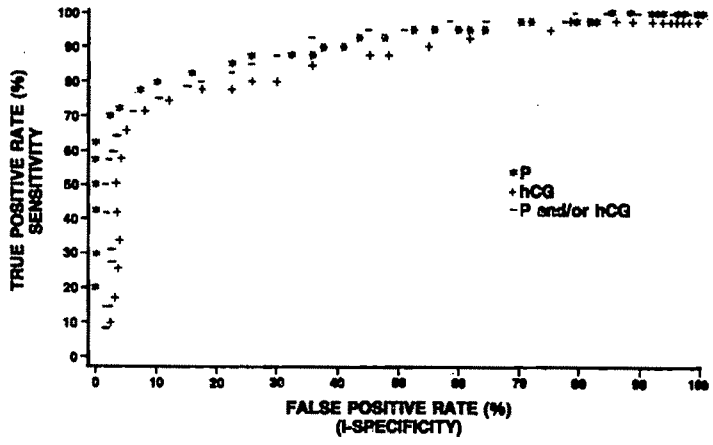

Fig. 1. Receiver-operator characteristic curves for three methods of pregnancy screening. Curve for progesterone *(P)*; *plus signs*, two hCG titers taken 48 hours apart; *minus signs*, progesterone combined with serial hCG titers.

method used to help diagnose ectopic pregnancy. Unfortunately, up to 21% of patients with ectopic pregnancy can have normally rising hCG titers.[1] Also, serial titers require at least two blood samples spaced by 48 hours, thereby delaying diagnosis by ≥2 days.

Cowan and his colleagues have used receiver-operator curves analysis, which graphically represents combinations of comparisons between sensitivity and specificity for a partial test. The better the test for detecting an abnormal condition, the further upward and to the left the curve will be displaced.

They have suggested that the discriminatory progesterone level should be 10 ng/ml; however, as can be seen in Fig. 1, at this level one is unable to determine whether a gestation is normal. The probability that the pregnancy is normal is not >80% until the progesterone concentration ≥18 ng/ml. This is inadequate for clinical practice. To use this test in clinical practice to predict normality, the test needs to be predictive in virtually 100% of cases. Thus, to predict pregnancy normality, the 25 ng/ml cutoff should be used.

At the 1988 American Fertility Society Meeting, our group reported the receiver-operator characteristic curve of 1120 first-trimester patients and compared the sensitivity and specificity of serial hCGs and progesterone at various cutoff levels.[2] The curves from our investigation are shown in Fig. 1, whereas Table I compares the sensitivity and specificity of progesterone at multiple cutoffs alone and in combination with an hCG rise of <66% over a 48-hour period with these data.

Should a single progesterone value replace serial hCG titers for ectopic pregnancy diagnosis? With our data, at ≥25 ng/ml, the sensitivity of a single progesterone level for detecting normal pregnancy is 0.970. The sensitivity rises only 0.022 with the addition of two hCG titers separated by 48 hours. In our series only one additional abnormal pregnancy would have been detected, with no additional ectopic gestations identified. If the screening progesterone level is ≥25 ng/ml, virtually all of these patients have viable intrauterine pregnancies. Only 1% to 1.5% of ectopic pregnancies are associated with progesterone levels of ≥25 ng/ml.

Table I. Comparison of sensitivities and specificities of single serum progesterone measurement at different values, serial hCG titers drawn 48 hours apart, and combination of serum progesterone and hCG titers

Characteristic	*Sensitivity*	*Specificity*
Progesterone <10 ng/ml	0.805	0.982
Progesterone <15 ng/ml	0.887	0.645
Progesterone <25 ng/ml	0.970	0.301
hCG <66% rise	0.887	0.516
Progesterone <10 ng/ml and hCG <66% increase	0.722	0.935
Progesterone <10 ng/ml or hCG <66% increase	0.970	0.473
Progesterone <15 ng/ml and hCG <66% increase	0.797	0.817
Progesterone <15 ng/ml or hCG <66% increase	0.977	0.344
Progesterone <25 ng/ml and hCG <66% increase	0.865	0.688
Progesterone <25 ng/ml or hCG <66% increase	0.992	0.129

The first international reference preparation of hCG was used.

To be of optimal clinical utility in predicting an abnormal pregnancy, any test would have a 100% specificity, but sensitivity would then be sacrificed. This level of specificity is mandatory if patients are to undergo endometrial curettage on the basis of an abnormal test result. We recently reported another series of over 1100 serum progesterone levels in patients with viable pregnancies.[3] The lowest serum progesterone level associated with a viable pregnancy was 5.1 ng/ml, leaving us to choose a cutoff value of 5.0 ng/ml. Therefore, if the serum progesterone value is <5.0 ng/ml, the preg-

nancy is nonviable in 100% of cases and the patient can undergo curettage without fear of interrupting a viable gestation.

On the basis of both our data and the data presented by Cowan et al. I believe the role of serum progesterone in clinical practice appears to be that of a screening tool for both normal and abnormal pregnancies. If the screening progesterone level is ≥25 ng/ml, the patient can be reassured that the pregnancy is viable in >95% of cases; if the progesterone level is <5.0 ng/ml, the pregnancy is considered nonviable. Patients can undergo evacuation of the uterus without fear of interrupting a viable pregnancy. On the other hand, if the serum progesterone level is ≥5 but <25 ng/ml, further testing, including serial hCG titers and transvaginal ultrasonography, is necessary.

This study is an excellent contribution to our body of knowledge concerning the role of serum progesterone screening. I congratulate Dr. Cowan and colleagues on their work.

The following questions are offered for discussion: (1) Do the authors screen all pregnant patients with a single serum progesterone level or only those patients with symptoms or risk factors for ectopic pregnancy? (2) Do the authors feel comfortable basing their results on only 40 normal and 34 abnormal pregnancies, of which only 18 were ectopic pregnancies?

Dr. Asghar Afsari, West Bloomfield, Michigan. Predicting the well-being of an early pregnancy from one or more maternal serum hormones has been the subject of many investigations. When multiple parameters have been used to better appreciate the diagnostic significance of each, the receiver-operator characteristic curve has been used. It is shown that the serum progesterone level is the single most important predictor of pregnancy viability.[1]

Dr. Cowan and his colleagues have tried to demonstrate the performance of serum progesterone levels for the predictive value and efficiency level at various concentrations. A cut-off point of 10 ng/ml is suggested to be an optimal discriminatory level to differentiate between a normal versus an abnormal pregnancy. However, pragmatically speaking, a sensitivity of 59% as claimed by the authors is not a desirable level to comfortably counsel patients. I agree with the authors that a cut-off between 9 and 14 ng/ml may be a maximum efficiency level for detection of abnormal and normal conditions, although the higher the progesterone level the better the predictive chance to have an intact normal intrauterine pregnancy. Furthermore, the test is 100% predictive of an abnormal pregnancy when the level of serum progesterone is ≤6 ng/ml, as has been demonstrated by the other authors earlier. It is also further apparent from the manuscript that there is always an overlap of serum progesterone concentrations in normal and abnormal pregnancies. The critical level where abnormal and normal test results cross is at a serum progesterone level between 14 and 15 ng/ml, at a predictive value of 79%. Because of this, monitoring of early pregnancies by transvaginal ultrasonography and prompt interpretation of these data and serial serum B-hCG are important. The last two parameters in conjunction with serum progesterone levels will further offer to confirm the differential diagnosis between tubal pregnancy and abortive intrauterine gestation.

As a side remark, Dr. Cowan and his coauthors have made a point that by using the receiver-operator characteristic curve they have been able to avoid an empiric cutoff of the serum progesterone level. The detailed and elaborate monograph by Charles E. Metz clearly explains, "The ROC curve is shown to be a simple, yet complete empirical description of threshold effect, indicating all possible combinations of the relative frequencies of the various kinds of correct and incorrect decisions."[2]

I agree with the authors that an optimal serum progesterone cutoff point would vary depending on the reagents, assay methods, and kits used in various laboratories. Additionally, perhaps this sort of clinical interpretation would require a larger amount of patients.

Finally, I have several questions for the authors. (1) In patients with tubal pregnancies, what was the percentage of rupture? Was a single serum progesterone level as critical as multiple serum measurements and has there been any time delay to reach a diagnosis as a result of this phenomemon? (2) Did the estimated gestational age of pregnancy from LMP influence the overall serum progesterone concentration? (3) What was the outcome of normal pregnancies whose serum progesterone concentration was <15 and ≥10 ng/ml? Was there any treatment rendered and what was the percentage of babies taken home?

Dr. C. Brandon Chenault, San Antonio, Texas. I wonder about the variations in laboratory in terms of interpreting these parameters.

Dr. Cowan (Closing). Dr. Stovall I think has focused on the controversy of serum progesterone measure-

ments in trying to determine the presence or absence of abnormal pregnancies. We do not use this test to make that determination. We use this test to make a determination of a risk. I think that if you're going to use the test to say whether the patient has an abnormal or a normal pregnancy, you need to use parameters that give you 100% predictability.

There are two important things that you can derive from the receiver-operator characteristic. One is information about what that value means for the application to your clinical population, and the second is other tests from other groups. Other studies or new information that you may put into your data base can be applied with the same type of interpretation.

This analysis was a retrospective analysis. We screen our patients with hCG doubling and ultrasonography, but we retrospectively analyzed the progesterone once we knew what their diagnosis was. We are confident with the small numbers; they are consistent with Dr. Stovall's larger numbers. Our confidence is derived from the statistical ability to compare information from new studies with the ROC analysis.

To address Dr. Stovall's and Dr. Sokol's comments, I agree that there still needs to be the acid test. We must move to the clinical arena and ask the question, "Can we use serum progesterone to screen or detect the abnormal condition that we can retrospectively analyze in a computational model?" Dr. Stovall has published two reports that have addressed the application of that type of testing.

To answer Dr. Afsari's questions, none of our patients had ruptured ectopic pregnancies. All were diagnosed early in the course of their condition with hCG monitoring and ultrasonography. There were no delays based on serum progesterone measurements, and all patients received treatment with either laparoscopic surgery or methotrexate on the basis of the patient's preference.

The time from the LMP does influence the serum progesterone concentration in both normal and abnormal pregnancies. A linear regression model of progesterone concentrations over time shows that time negatively influences the serum progesterone level in the first 49 days of pregnancy. Dr. Afsari asked about the pregnancy outcome of the patients with normal pregnancies and progesterone values <15 or <10 ng/ml. We provided no treatment for these patients. They did not receive supplemental progesterone. All of these were normal pregnancies, and the rate of babies taken home was 100% for this group of patients.

Dr. Chenault asked about laboratory variations. This is a very important consideration. In comparing progesterone values, each laboratory or group of investigators will need to derive their particular progesterone cutoff. With receiver-operator characteristic analysis the aspects of each particular assay and its variability can be obviated by the ability to return to the receiver-operator characteristic analysis and simply determine how a new population compared with, for example, our population or Dr. Stovall's population.

And last, for Dr. Sokol, I agree. It's time to take this type of information to the clinical environment to see if we can do as well as we think we might be able to do.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1992 issues from the Publisher, at a cost of $68.00 for domestic, $95.76 for Canada, and $91.00 for international for Vol. 166 (January-June) and Vol. 167 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351, or (314) 453-4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Prevalence of out-of-phase endometrial biopsy specimens

Albert J. Peters, DO, Riley P. Lloyd, MD, and Carolyn B. Coulam, MD
Indianapolis, Indiana

OBJECTIVE: We attempted to determine the prevalence of out-of-phase endometrial biopsy specimens among fertile and infertile women and women with recurrent pregnancy loss, histologic dating of biopsies was compared with four reference points for expected ovulation. These reference points included last menstrual period, next menstrual period, luteinizing hormone testing, and ultrasonographic documentation of ovulation.
STUDY DESIGN: Four hundred eight-five endometrial biopsies were performed 7 days after documented ovulation-based ultrasonographic evidence for follicle collapse. The histologic dating was referenced to the last menstrual period, next menstrual period, and ultrasonographic documentation of ovulation. One hundred thirty-two of these women also performed urinary luteinizing hormone surge testing before ovulation and serum progesterone determinations. A comparison of the prevalence of out-of-phase biopsy specimens among groups was determined with the χ^2 test and Fisher's exact test.
RESULTS: The prevalence of out-of-phase endometrial biopsy specimens ranged from 42% when last menstrual period was ued to 26% with next menstrual period, to 21% with luteinizing hormone testing, and to 4% with ultrasonographic documentation of ovulation. Serum progesterone values among women with a diagnosis of out-of-phase biopsy specimens by any of the reference dates progesterone were similar to those with in-phase biopsy specimens.
CONCLUSION: The accuracy of histologic endometrial dating was best determined by ultrasonographic monitoring rather than by last menstrual period, next menstrual period, or luteinizing hormone testing in infertile populations and in those with recurrent pregnancy loss. Additionally, because no significant difference in out-of-phase biopsy specimens exists between fertile and infertile patients and recurrent pregnancy loss, those with the role of this procedure is called into question. (Am J Obstet Gynecol 1992;166:1738-46.)

Key words: Out-of-phase biopsy specimens, ovulation, endometrial biopsies, infertility, recurrent pregnancy loss

Luteal phase defect was initially defined as a defective corpus luteum with insufficient progesterone production, whether in amount or duration.[1] Since its first description, there has been a lack of consensus as to the role of luteal phase defect as a cause of reproductive failure. Disagreement has primarily been a result of a lack of controlled studies to determine whether correction of the luteal phase defect is of value in treating patients with reproductive problems. Accurate conclusions about treatment must be preceded by accurate diagnosis of the defect. Diagnosis by serum progesterone level, menstrual history, and shortened luteal phase have been inadequate. The accepted standard of diagnosis remains an endometrial biopsy with histologic dating and the criteria established by Noyes et al.[2] Traditionally, histopathologic dating has been compared to onset of next menstrual period; dating is started at day 28 and counted backward.[1, 3] The day of ovulation is considered to be day 14 in a normal cycle. The conventional diagnosis of luteal phase defect has been made by demonstrating a discrepancy between histologic dating and menstrual history by 2 days.[1, 3]

More recently, measurement of luteinizing hormone (LH) or demonstration of ovarian follicular rupture with ultrasonography has allowed a more objective documentation of ovulation.[4] In a recent study,[5] when histologic dating of the endometrium was correlated with postovulatory duration as determined by daily transvaginal ultrasonographic scanning, serum LH determination, basal body temperature, and subtraction of 14 days from onset of next menstrual period in 13 fertile women, the accuracy of dating was significantly better with days from ovulation determined by ultrasonography.

The purpose of this study was to compare the frequency with which the diagnosis of out-of-phase biopsy specimens is made on the basis of dating of the endometrial biopsy specimen from the onset of the last and the next menstrual cycles and from the time of ovulation documented by urinary LH testing and serial ultrasonographic examinations. The prevalences of out-of-phase biopsy specimens with each of these ref-

erence points was compared among infertile women, women experiencing recurrent pregnancy loss, and fertile women. These results are also compared with midluteal phase serum progesterone concentrations. The results of this study will be useful in managing cases in which patients are being evaluated for reproductive failures.

Material and methods

Patients. Four hundred eighty-five women were studied; of these, 340 were infertile, 115 had experienced recurrent pregnancy loss, and 30 were fertile.

Infertility was defined as the inability to achieve desired pregnancy after 1 year of unprotected intercourse. The evaluation of couples presenting with infertility consisted of documentation of ovulation by means of urinary LH testing, monitoring of folliculogenesis with serial ultrasonographic examinations, evaluation of luteal phase serum progesterone concentrations, and endometrial biopsies. Sperm availability was documented by semen analysis and the hamster egg penetration assay. Male factor as a cause of infertility was diagnosed if the sperm concentration was <20 million spermatozoa per milliliter, motility and/or normal morphologic characteristics were <50%, and/or the hamster egg penetration assay revealed <12% penetration. Tubal factor as a cause of infertility was assessed by hysterosalpingography and pelvioscopy. To be assigned a diagnosis of tubal factor as a cause of infertility, a woman had to have tubal occlusion documented by hysterosalpingography and pelvioscopy, peritubal adhesions displayed at the time of pelvioscopy, or a history of having undergone a previous tuboplasty. The diagnosis of endometriosis was made by demonstration of endometrial implants within the peritoneal cavity at the time of pelvioscopy. Unexplained infertility was diagnosed if the evaluation yielded no discernible cause.

Recurrent pregnancy loss was defined as two or more consecutive spontaneous abortions. Evaluation of couples with recurrent pregnancy loss included chromosome analysis of both partners, hysterosalpingography and hysteroscopy of the female partner, luteal phase serum progesterone concentration and endometrial biopsies; autoantibody testing, including tests for antinuclear antibodies and antiphospholipid antibodies (e.g., anticardiolipin and antiphosphatidylserine antibodies), activated partial thromboplastin time, assays for the presence of maternal antipaternal lymphocytotoxic antibodies[6]; mixed lymphocyte culture; and human leukocyte antigen typing of both partners.

The control group was composed of 30 volunteer women from the Indianapolis community. Complete medical and obstetric histories were obtained from each woman. A fertile control was defined as a woman who had had two or more successful pregnancies and who was able to conceive a desired pregnancy within 1 year of unprotected intercourse. Volunteers with three or fewer pregnancies have had no spontaneous abortions and also must have had at least two children. Volunteers with four or more pregnancies may have had one spontaneous abortion. However, the most recent pregnancy must have been normal, and these women must have been able to meet the other criteria for women with three or fewer pregnancies.

Menstrual history. Each woman had her menstrual history, including the onset of her last menstrual period (LMP) and the next menstrual period during the monitored cycle, recorded. When the LMP was used as a reference point by which to date the endometrial biopsy specimen, ovulation on day 14 of a 28-day menstrual cycle was assumed. When the next menstrual period was used as a reference of the day of endometrial biopsy, a 14-day luteal phase (and hence ovulation) was assumed to have occurred 14 days before the onset of the next menstrual period.

Endometrial biopsy. All women had an endometrial biopsy performed during the luteal phase of the menstrual cycle 7 to 10 days after documented ovulation on the basis of ultrasonography. Biopsy specimens were obtained with a Novak curette, and the tissue was fixed in a 10% neutral buffered formalin solution and embedded in paraffin blocks. Hematoxylin and eosin–stained sections were examined and dated according to the criteria of Noyes et al.[2] The histologic dating was compared with the cycle day of the biopsy according to the onset of the LMP, the onset of the next menstrual period, the urine LH level, and ovulation on the basis of ultrasonographic monitoring. Out-of-phase biopsy specimens were diagnosed if the histologic appearance of the endometrial biopsy specimen was >2 days out of phase from the day on which the biopsy was performed.

LH testing. LH testing was done by qualitative means using the Q Test ovulation kit (Clay Adams, Parsippany, N.J.). This is a monoclonal antibody enzyme immunoassay dipstick designed to visually detect human LH in urine specimens. Sensitivity of the Q Test is 97% relative to reference radioimmunoassay ≥60 mIU/ml) for urine samples. Patients were instructed to collect first-morning urine specimens daily from cycle day 10 until an LH surge was detected. The dipsticks were blotted and included in the patient's medical record. Ovulation was assumed to occur within 24 hours of LH surge.

Ultrasonographic monitoring of ovulation. Ultrasonographic examination was begun on days 8 to 10 of the menstrual cycle and continued every 2 to 3 days until follicle rupture was documented. The criteria for ultrasonographic evidence of ovulation have been described by Hill et al.[4]: The dominant follicle shows loss

Table I. Clinical characteristics of 485 women participating in endometrial biopsy study

Women	Age (yr)		Gravidity	
	Mean	Range	Mean	Range
Infertile	32	21-42	0.9	0-5
Recurrent spontaneous abortion	32	21-42	4.0	2-11
Fertile	31	22-37	3.0	2-5

Table II. Frequency of causes of infertility diagnosed in 340 couples

Cause of infertility	No.	%
Tubal factor	120	35
Unexplained	106	31
Male factor	76	23
Endometriosis	38	11
TOTAL	340	100%

of clear demarcation of its walls, there is a decrease in follicular size, and intrafollicular echoes occur. In addition, increased volume of fluid in the cul-de-sac suggested ovulation.

Serum progesterone determinations. Blood was drawn from each woman at the time of endometrial biopsy. Each blood specimen was evaluated for serum progesterone concentration with a radioimmunoassay (Diagnostic Products Corporation, Los Angeles).

Comparative analysis. The prevalence of diagnosis of out-of-phase biopsy specimens on the basis of histologic dating of the endometrium from the LMP and the next menstrual period was compared with the frequency of diagnosis of out-of-phase biopsy specimens on the basis of ovulation documented by LH testing and/or ultrasonographic monitoring. The χ^2 test and Fisher's exact test were used. The prevalence of diagnosis of luteal phase defect on the basis of mean midluteal phase progesterone concentration for each group was determined by Fisher's exact test. These comparisons were made among infertile women, women experiencing recurrent pregnancy loss, and fertile control women.

Results

Patients. Table I summarizes the clinical characteristics of the women participating in the study. The mean age of the infertile women was 32 years (range 21 to 42 years) in women with recurrent pregnancy loss, it was 32 years (range 21 to 42 years), and in fertile women it was 31 years (range 22 to 37 years). The mean gravidity among women with recurrent spontaneous abortion was 4 (range 2 to 11); among fertile control women, 3 (range 2 to 5); and among infertile women, 0.9 (range 0 to 5).

The frequency of diagnosis of infertility is summarized in Table II. Of the 340 infertile couples studied, 120 (35%) had the diagnosis of tubal factor as a cause of infertility; 106 (31%), unexplained infertility, 76 (23%), male factor, and 38 (11%), endometriosis. Those women who had a diagnosis of ovulatory factor as a cause of infertility were not included in this study.

Prevalence of out-of-phase biopsy specimens. The prevalence of out-of-phase endometrial biopsy specimens among infertile women, women experiencing recurrent pregnancy loss and fertile women is summarized in Figs. 1 to 4.

Among 340 infertile women, 146 (43%), 92 (27%), and 12 (3.5%) displayed histologic evidence of out-of-phase endometrial biopsy specimens when the LMP, the next menstrual period, and ultrasonographic results, respectively, were used as reference points for ovulation (Fig. 1). Urinary LH testing was performed by 93 of the 340 infertile women, of whom 20 (22%) had histologic evidence of out-of-phase endometrial biopsy specimens. χ^2 analysis revealed that significantly fewer out-of-phase biopsy specimens were diagnosed when ultrasonography was used as a reference for histologic dating rather than the LMP, the next menstrual period, or LH testing ($p < 0.05$), but no significant difference was noted between results from the use of the next menstrual period and LH testing (Fig. 1).

Fig. 2 demonstrates the prevalence of out-of-phase endometrial biopsy specimens among 115 women experiencing recurrent spontaneous abortions. Among these 115 women, 45 (38%), 28 (24%), and 6 (5%) had histologic evidence of out-of-phase endometrial biopsy specimens when LMP, the next menstrual period, and ultrasonographic results, respectively, were used as reference points for ovulation. When urinary LH testing was performed by 24 women, 5 (20%) had histologic evidence of out-of-phase endometrial biopsy specimens. Again, χ^2 analysis revealed significantly fewer out-of-phase biopsy specimens when ultrasonography was used as the reference for histologic dating rather than the LMP, the next menstrual period, or LH testing ($p < 0.05$).

Among 30 fertile women, 15 (50%), 9 (32%), and 3 (10%) had histologic evidence of out-of-phase endometrial biopsy specimens when the LMP, the next menstrual period, and ultrasonographic results, respectively, were used as reference points for ovulation (Fig. 3). Fifteen of the 30 fertile control women performed urinary LH testing as a reference for ovulation. As a result of urinary LH testing, 4 of 15 (26%) demonstrated out-of-phase endometrial biopsy specimens. Among fertile controls, Fisher's exact test demonstrated significantly fewer out-of-phase biopsy speci-

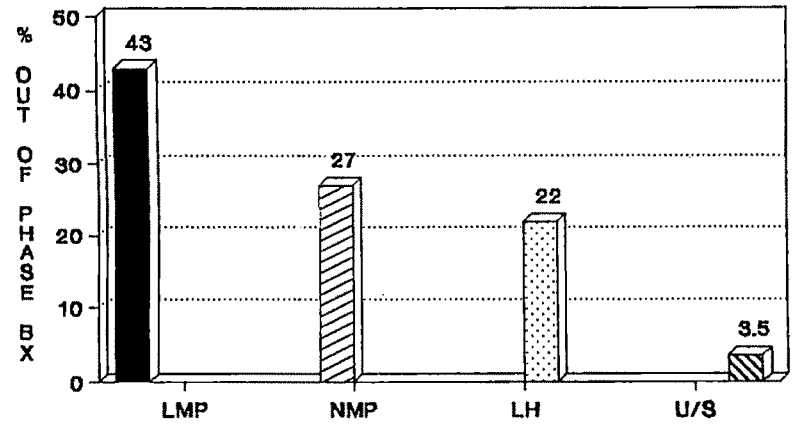

Fig. 1. Prevalence of out-of-phase endometrial biopsy specimens among 340 infertile women; biopsies are on basis of onset of LMP, next menstrual period *(NMP)*, urinary LH testing, and documentation of follicle rupture by ultrasonographic examination *(U/S)*.

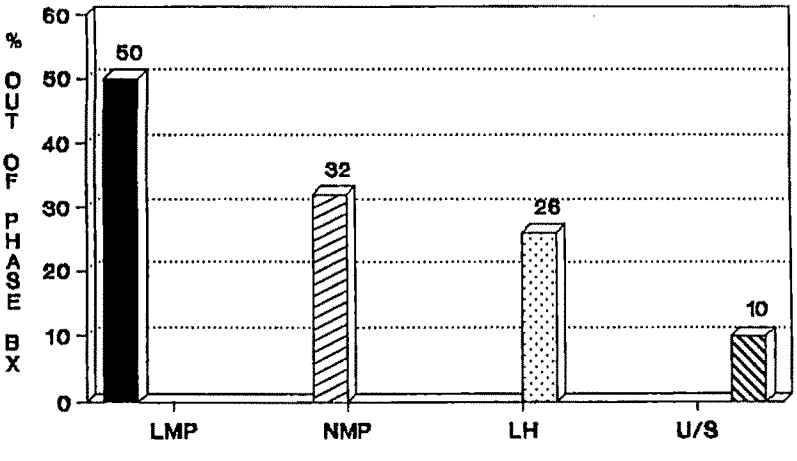

Fig. 3. Prevalence of out-of-phase endometrial biopsy specimens among 30 fertile women on basis of onset of LMP, next menstrual period *(NMP)*, urinary testing, and documentation of follicle rupture by ultrasonography examination *(U/S)*.

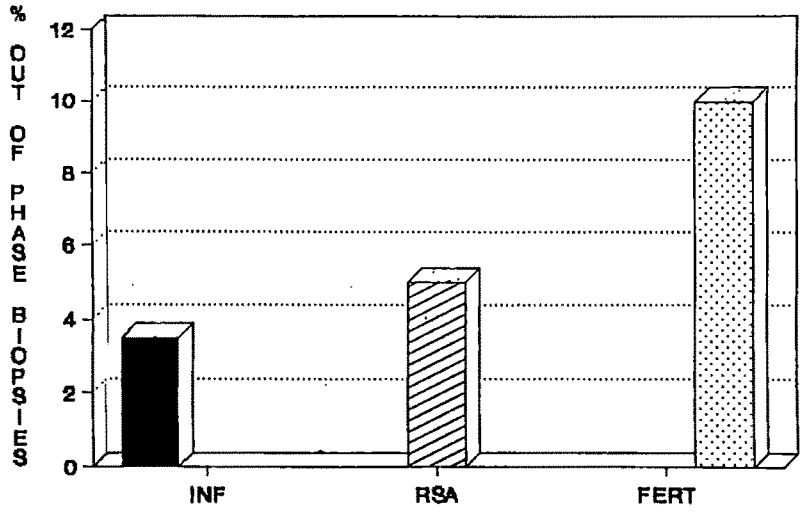

Fig. 4. Prevalence of out-of-phase endometrial biopsy specimens among 340 infertile women *INF*, 115 women experiencing recurrent spontaneous abortion *(RSA)*, and 30 fertile women *(FERT)* when ultrasonographic documentation of ovulation was used to compare dating of endometrial biopsy specimens.

Table III. Prevalence of out-of-phase endometrial biopsy specimens among infertile women by specific cause of infertility

	Prevalence of out-of-phase biopsy specimens							
	LMP		*NMP*		*LH*		*US*	
Cause of infertility	*No.*	*%*	*No.*	*%*	*No.*	*%*	*No.*	*%*
Explained	100	42	71	30	14	20	9	4
Tubal factor	54	45	38	32	7	21	3	2
Male factor	36	47	27	36	7	25	5	6
Endometriosis	10	26	6	16	0	0	1	2
Unexplained	46	43	21	20	6	24	3	3
TOTAL	146	43	92	27	20	22	12	4
Significance					$p < 0.05$*		$p < 0.05$*	

NMP, Next menstrual period; *US*, ultrasonographic testing.
*Significantly fewer out-of-phase biopsy specimens were observed when either LH or ultrasonographic testing was used as the reference for histologic dating of biopsy specimens.

mens when ultrasonography was used as a reference for histologic dating rather than the LMP ($p < 0.05$).

Fig. 4 summarizes the prevalence of out-of-phase endometrial biopsy specimen among 340 infertile women, 115 women experiencing recurrent spontaneous abortion, and 30 fertile women when ultrasonographic documentation of ovulation was used as a point of reference in comparison of the histologic findings of the endometrial biopsy specimen. The prevalence of out-of-phase endometrial biopsy specimens was 3% in infertile women, 5% in women experiencing recurrent spontaneous abortion, and 10% in fertile women. A χ^2 analysis revealed no significant difference among these groups ($p > 0.05$).

Further analysis of the prevalence of out-of-phase endometrial biopsy specimens by specific cause of infertility is shown in Table III. The prevalence of out-of-phase endometrial biopsy specimens was 4% among women with an explained cause of infertility and 3% among those with an unexplained cause when ultrasonographic documentation of ovulation was used as a reference for comparison of the histologic findings of the endometrial biopsy (Table III).

Serum progesterone determinations. Mean serum midluteal progesterone concentrations from 93 infertile women, 24 women experiencing recurrent pregnancy loss, and 15 fertile women are presented in Table IV.

When mean serum progesterone concentrations from infertile women with out-of-phase endometrial biopsy specimens were compared with serum progesterone values from infertile women with in-phase endometrial biopsy specimens, no differences were observed. Sixty-eight of 93 infertile patients had an explainable cause of infertility (i.e., tubal factor, male factor, endometriosis). Of these 68 explained infertile patients, 8 had an out-of-phase endometrial biopsy specimen and 60 had in-phase biopsy specimens when ultrasonographic results were used to determine ovulation. The mean serum progesterone concentrations were 16.0 and 11.7 ng/ml, respectively. No significant difference exists between these serum progesterone values ($p > 0.05$). The causes of infertility in 25 of the 93 infertile patients were unexplained. Two of 25 patients with unexplained infertility had out-of-phase biopsy specimens with a mean serum progesterone level of 14.7 ng/ml. Twenty-three of 25 patients with unexplained infertility had in-phase biopsy specimens with

Table IV. Comparison of mean serum midluteal progesterone concentrations and prevalence of out-of-phase endometrial biopsy specimens among women with various causes of infertility, women with a history of recurrent pregnancy loss, and fertile control women

Endometrial biopsy specimens	*No.*	*Mean serum progesterone (ng/ml)*		*Significance**

*Fisher's exact test demonstrates no significant difference in mean serum midluteal progesterone values between in-phase and out-of-phase endometrial biopsy specimens for patients with explained infertility, unexplained infertility, or recurrent pregnancy loss when compared with fertile control patients.

†Numbers in parentheses are numbers of biopsies that represent this mean midluteal serum progesterone concentration.

a mean progesterone value of 12.5 ng/ml. No significant difference exists between these mean serum progesterone values ($p > 0.05$) by Fisher's exact test. Among 24 women experiencing recurrent pregnancy loss, 1 had an out-of-phase endometrial biopsy specimen and had a serum progesterone concentration of 2.4 ng/ml. Twenty-three of 24 patients had in-phase biopsy specimens with a mean serum progesterone level of 13.8 ng/ml. Again, no significant difference exists between mean serum progesterone levels ($p > 0.05$) by Fisher's exact test. Fifteen of 30 fertile control patients were evaluated for a serum progesterone concentration 7 to 10 days after documented ovulation. Two of 15 fertile control women had out-of-phase biopsy specimens with a mean progesterone concentration of 10.6 ng/ml. The remaining 13 women had in-phase endometrial biopsy specimens for a mean progesterone value of 10.3 ng/ml. No significant difference existed here, either ($p > 0.05$). Collectively, 132 women had midluteal phase progesterone concentrations determined, and 13 (10%) displayed out-of-phase endometrial biopsy specimens; 119 (90%) had in-phase endometrial biopsy specimens. No correlation between midluteal phase progesterone concentrations and out-of-phase endometrial biopsy specimens was observed.

Comment

Analysis of results from this study indicate that the frequency of diagnosis of luteal phase defect among women varies markedly as a result of the point of reference used to date the endometrial biopsy specimen. Because of the variance in the length of the follicular phase of the menstrual cycle, dating the endometrial biopsy specimen with reference to the onset of the next menstrual period has been recommended[5] and has become a standard of practice. Although dating the endometrial biopsy specimen by means of the onset of the next menstrual period diminished the frequency of diagnosis of out-of-phase biopsy specimens among couples experiencing infertility compared with the results of dating by means of the onset of the LMP, this accepted method yielded a much higher prevalence of out-of-phase biopsy specimens than did dating according to documented ovulation by ultrasonography.

Our findings confirm observations by Shoupe et al.,[5] who found that the accuracy of histologic endometrial dating was significantly better when ovulation was determined by ultrasonographic monitoring rather than by onset of the next menstrual period, the basal body temperature, or the serum LH value. The prevalence of diagnosis of out-of-phase biopsy specimens fell from 27% to 3.5% among infertile women and from 38% to 5% among women experiencing recurrent spontaneous abortion when ultrasonography, rather than the onset of the next menstrual period was used to document ovulation.

The prevalence of diagnosis of luteal phase defect among infertile patients has been estimated to be 5%,[7-9] which is consistent with the prevalence of out-of-phase biopsy specimens in the current study of couples with unexplained infertility when ovulation documented by ultrasonographic examination was used to date the endometrial biopsy specimen. In contrast, an inadequate luteal phase has accounted for 23% to 67%[10-14] of diagnosed causes of recurrent spontaneous abortions, which is consistent with the results presented here when menstrual dates were used to interpret the endometrial biopsy specimen. However, these figures are substantially higher than those observed when documented ovulation was used to date the endometrial

biopsy specimen. In an evaluation of 195 Norwegian couples with a history of recurrent spontaneous abortion, 5% showed evidence of luteal phase defect.[15] Although an argument has been advanced that progesterone deficiency must be corrected before implantation to prevent recurrent abortion,[1, 10, 16] no placebo-controlled trial has proved this hypothesis. The data presented here suggest that out-of-phase endometrial biopsy specimens and possibly luteal phase defect are not common causes of recurrent pregnancy loss.

In spite of the modality used, the prevalence of diagnosis of out-of-phase endometrial biopsy specimens was as high or higher in the fertile control population when compared with two populations experiencing reproductive failures. The prevalence of out-of-phase biopsy specimens among fertile women was 10% when ultrasonography was used to document ovulation. Others have documented a high prevalence of luteal phase defect among normally cycling women.[5, 17-19] A prevalence of luteal phase defect of 23% has been reported in women with completely normal follicular and periovulatory phases.[18] Implantation is the only gold standard for endometrial adequacy. Endometrial biopsy specimens taken during conceptional cycles were diagnosed as showing luteal phase defect in 23%.[20]

An explanation for the out-of-phase endometrial biopsy specimen in normal women is the inaccuracy of the histologic dating of the endometrium.[21] The accuracy of an endometrial biopsy specimen in the diagnosis of luteal phase defect has been reported to be 25% to 35%.[21, 22] This low accuracy rate has been attributed to improper acquisition of tissue, variability in the method of documentation of ovulation, and reproducibility of reading of the endometrial biopsy specimen by various pathologists. In their original dating criteria Noyes et al.[2] commented that they were "somewhat arbitrary" and that their method represented "sequential phases rather than actual days of the cycle." When these investigators analyzed the accuracy of dating in 300 women in the luteal phase, only 14% of these women menstruated on the day predicted (12% later and 74% earlier than expected). The error ranged from 12 days early to 8 days late; the mean (±SD) was 1.81 ± 2.33 days. The authors concluded that dating is a "better gauge of progesterone effect than it is a prediction of onset of menses."[2]

Subsequent data supported the conclusions of the early study[5] that the endometrial biopsy specimen more accurately represents a progesterone effect than a specific day in the menstrual cycle The diagnosis of luteal phase defect has been made by endometrial biopsy because this method of diagnosis has been thought to reflect the total effect of the endocrine events of the menstrual cycle.[10] Midluteal phase progesterone concentrations have been reported to be inaccurate in diagnosing luteal phase defect because of sporadic fluctuations in secretion of progesterone by the corpus luteum and because many investigations have demonstrated a lack of correlation between endometrial histologic characteristics and peak serum progesterone levels.[21, 23]

In this study no correlation between midluteal phase progesterone concentrations and out-of-phase endometrial biopsy specimens was observed; this confirms the previous reports.[23, 24] However, analysis of the data suggests that out-of-phase endometrial biopsy specimens are not correlated with reproductive performance. Therefore midluteal phase serum progesterone concentration may be as accurate as endometrial biopsy in defining postovulatory corpus luteum function. Although the corpus luteum is important for successful reproduction in mammalian species, the diagnostic methods that pertain to the effects of functional defects on reproductive performance have been questioned.

Editors' note: This manuscript was revised after these discussions were presented.

Discussion

Dr. E. James Aiman, Milwaukee, Wisconsin. "Out-of-phase endometrial biopsy specimens are not correlated with reproductive performance." This quotation from the authors' manuscript serves as their hypothesis, their null hypothesis in statistical terms. To accept or reject this hypothesis, the authors obtained one endometrial biopsy specimen from each of 485 women, 340 of these women were infertile, 115 had had repeated pregnancy losses, and 30 were fertile women who served as control subjects. To draw conclusions regarding their stated hypothesis, the authors correlated their histologic findings from this single midluteal endometrial biopsy specimen with five measures of ovulation: each woman's last menses, her next menses, ultrasonographic evidence of ovulation, urinary LH testing, and midluteal serum progesterone concentrations. They used a standard definition of out-of-phase endometrium: 2 days.

To decide whether the authors have performed a study that allows them to accept their stated hypothesis, I will use a metaphor offered by Peterson and Kleinbaum.[1] This is a metaphor of a marksman's target. Precision is the proximity of the data to the bull's-eye. Validity deals with whether the appropriate data are aimed at the right target. By including infertile women, women with repeated pregnancy losses, and a fertile group of women as controls, the authors have three targets that are appropriate together. In the correlation of endometrial histologic factors with five measures of ovulation in these three groups of women the authors have performed a valid study, although the number of fertile women as control subjects (30) is a much smaller sample than those in the other two groups.

It is the precision that weakens the ability of the authors to accept their hypothesis that out-of-phase endometrial biopsy specimens are not correlated with reproductive performance. First, it is somewhat curious that there is an apparent single etiologic factor in all 340 infertile couples, whereas 10% to 20% would be expected to have two or more apparent impediments to fertility. This suggests a selection bias, or perhaps an editorial decision by the authors to categorize these women according to the most prominent cause of infertility.

Precision in the interpretation of the endometrial biopsy specimens may be a significant source of error in any study of endometrial dating. The authors do not state in their manuscript who interpreted the endometrial biopsy specimens whether a single person interpreted all endometrial biopsy specimens, or if the interpreter was blinded to the clinical diagnosis. The precision of interpretation could be tested and probably improved if each biopsy were read a second time by the same interpreter, if that person were unaware of his or her initial interpretation. The precision of interpretation could be tested and probably improved if each biopsy were interpreted by a second person. Scott et al.[2] reported that the diagnosis of in-phase or out-of-phase endometrium was changed in 22% of women when the endometrium was dated by a second person.

Also contributing to the imprecision is the authors' definition of an out-of-phase endometrium by a discrepancy of 2 days. In their manuscript the authors do not state how many of the out-of-phase endometria demonstrated a 2-day lag and how many exhibited a 2-day advance of the number of days after ovulation. The inclusion of multiple histologic criteria from both endometrial stroma and glands may add to the imprecision. By means of quantitative histologic techniques, Li et al.[3] observed that women with unexplained infertility had a significant deviation from normal in only 5 of 14 histologic features. These five features were in the glands; none was in the stroma. Thus the imprecision of the interpretation of endometrial histologic factors is a combination of the "noise" of interpreting multiple histologic events plus interobserver variation.

The authors used serial ultrasonographic measurement to determine the day of ovulation. However, the performed ultrasonographic examinations only every 2 to 3 days, which means that they could be off by as many as 3 days. Because the authors used ultrasonographic criteria to determine the day of ovulation, it is not surprising that an out-of-phase endometrium was found much less frequently with ultrasonographic dating as opposed to the date of the last menses, the date of the next menses, urinary LH testing, or midluteal progesterone concentrations. This interval of ultrasonographic determination potentially adds to the imprecision of their data.

The authors obtained a single serum progesterone concentration on the day of the endometrial biopsy, 7 to 10 days after ultrasonographic evidence of ovulation. Obtaining a single measurement over this range of days ignores the expected daily changes in progesterone concentration and also ignores the variations in the

serum progesterone secretion within a specific day. Nonetheless, the authors' finding that serum progesterone concentrations were similar in all groups of women, regardless of diagnosis or endometrial histologic factors, is similar to that reported by Glazener et al.[4] Olive et al.[5] correlated hourly serum progesterone concentrations over 24-hour period with endometrial histologic factors and concluded that neither endometrial biopsy nor serum progesterone concentration alone is sufficient to establish a diagnosis of luteal phase deficiency. Further, they concluded that pooled morning serum progesterone concentrations provided the optimal predictive value for endometrial biopsy results.

From any discussion it may appear that I find little of value in this manuscript. Quite the contrary is true. Peters and coauthors are to be commended for collecting data on a large number of women and for rigorously defining their selection criteria. From their data and the data of others whom they cite in their manuscript, the authors are justified in concluding that luteal phase deficiency is a difficult diagnosis to make, is found in percentage of women with normal reproduction, and therefore is of uncertain significance in women with repeated pregnancy loss or infertility. Because of the design elements in their study that contribute to a decreased precision, the authors can rightfully suggest but have not proved that "out-of-phase endometrial biopsy specimens are not correlated with reproductive performance."

Dr. M. Wayne Heine, Tucson, Arizona. The title of the report should probably be changed to "The Accuracy of Timing of Ovulation." The authors use the criteria described by Noyes et al.[1] These authors described the criteria as being "somewhat arbitrary." Because of variance in histologic interpretation, one of the authors read all the slides. Their is the gold standard by which luteal phase function is evaluated. Li et al.[2] reported on 63 endometrial biopsy specimens read by the same pathologist on two separate occasions. There was exact agreement only 24% of the time. Those authors also reported that when two cycles in the same patient were evaluated there was agreement only 41% of the time. Here are questions for Dr. Peters: Who did the histologic interpretation? Were any patients evaluated for more than one cycle?

Some of our work on the evaluation of sleep patterns at various times of the menstrual cycle in "always regular women" showed that 15% of these cycles were anovulatory (unpublished observations). There may be considerable cycle-to-cycle variation. Peters et al. found that the "accuracy of dating" was significantly better when ultrasonographic monitoring was used. The histologic criteria described by Noyes et al.[1] used next menstrual period and not the estimated date of ovulation. Peters and associates used ultrasonographic testing every 2 to 3 days. Could this not give up to a 24- to 48-hour variation in histologic interpretation?

The authors of this study also used serum progesterone studies. Were all these obtained at the same time of the day from a single vein puncture?

None of the various methods used to describe the adequacy of the luteal phase really reflect function. As the authors stated, "implantation" is really the gold standard. The function of the corpus luteum is probably the result of follicular development during the follicular phase. Until we have a more "functional" test of adequacy of ovulation, might it not be more accurate to reevaluate the histologic criteria of Noyes et al.[1] and to use more accurate methods of timing ovulation, which would date the endometrium from the time of ovulation until the biopsy is performed? The authors have accomplished a tremendous amount of work and have a tremendous amount of information. They might want to reevaluate the timing of ovulation by ultrasonography and date the endometrium according to the number of days the biopsy was done after ultrasonographic evidence of ovulation.

Drug use or inadequate prenatal care? Adverse pregnancy outcome in an urban setting

Fredrik F. Broekhuizen, MD, John Utrie, DO, and Chris Van Mullem, RN
Milwaukee, Wisconsin

OBJECTIVE: This study analyzed the relationships between illicit drug use, low birth weight, adequacy of prenatal care, and perinatal mortality.
STUDY DESIGN: Perinatal outcome parameters in 23,926 deliveries between 1983 and 1990 were analyzed. Statistical analysis (χ^2 analysis) was applied for each year of study to separate the effects of inadequate prenatal care from illicit drug use.
RESULTS: Patients with drug use had a two to three times higher incidence of low birth weight and perinatal death. Drug use with more than five prenatal visits had a minimal effect on outcome; drug use with inadequate care was associated with a three times higher incidence of perinatal death and low birth weight.
CONCLUSION: Adequacy of prenatal care is a marker of "social chaos" and affects outcome more than drug use itself. (Am J Obstet Gynecol 1992;166:1747-56.)

Key words: Drug use, prenatal care, perinatal death, low birth weight

The frequency of illicit drug use during pregnancy has increased markedly in the last decade, especially in urban areas.[1-4] Drug use during pregnancy has been reported to be associated with adverse pregnancy outcome.[2, 5] An increase in the incidence of spontaneous abortion, renal and limb anomalies, preterm labor, and abruptio placentae has been associated with cocaine use.[3-8] Illicit drug use has been associated with inadequate prenatal care, low birth weight, increased perinatal mortality, and sudden infant death syndrome.[1, 4, 6, 7]

Illicit drug use during pregnancy in our own urban institution was ascertained in 1989 by an anonymous urine and questionnaire screening of 1000 patients.[9] This survey indicated that in our institution 15.9% of patients delivered used illicit drugs with crack cocaine (66%) the most common illicit drug. A total of 54% of perinatal drug users used multiple drugs and 84% smoked cigarettes and used alcohol.

This study aimed to analyze the trend in illicit drug use during pregnancy over an 8-year period and to analyze the relationships between illicit drug use, low birth weight, adequacy of prenatal care, and perinatal mortality in an urban perinatal center from 1983 to 1990.

Material and methods

Since 1983 our institution has collected perinatal data in a computerized data base, described previously.[10] A set of data, routinely used for birth certificate information, quality assurance, and clinical research projects, was collected on all births. Patients were accepted for inclusion in this study if their records contained complete information regarding birth weight, race, age, parity, number of prenatal visits, illicit drug use in pregnancy, cause of perinatal mortality, and assignment of preventability of perinatal death. In addition, all records had to indicate the presence or absence of diabetes mellitus, hypertension, a history of preterm birth, tobacco use, alcohol use, and congenital anomalies in the neonate.

Perinatal mortality was defined as fetal or neonatal death after 20 weeks' gestation or with birth weights >500 gm up to 28 days of neonatal life. Low birth weight was defined as birth weight <2500 gm. Potential preventability had been routinely assigned for each perinatal death by perinatal quality assurance criteria developed in our institution and applied since 1980. A perinatal death was deemed preventable if standard prenatal care was thought to have been able to prevent or modify the obstetric events leading to a perinatal death, thereby preventing the death. Drug use, in the context of this article, included illicit drugs only (opiates, marijuana, cocaine, amphetamines, PCP), and alcohol and tobacco use were not included in this category. Statistical testing was done for each year of the study by χ^2 analysis. A value of $p < 0.05$ was considered statistically significant. Multiple regression analysis was unfortunately impossible in our data setup. Wherever

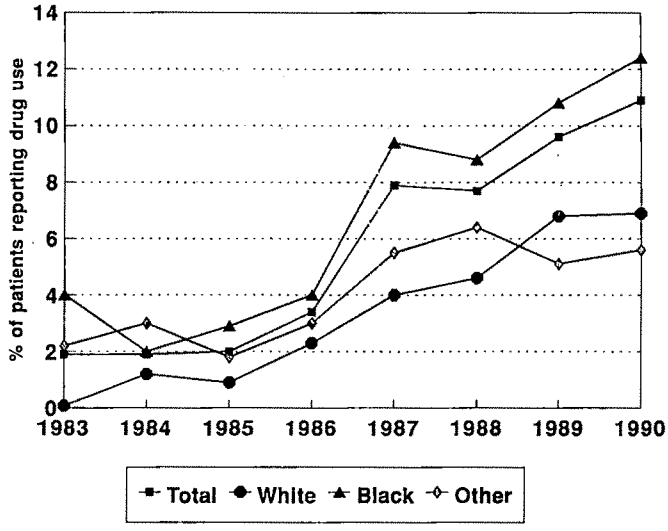

Fig. 1. Illicit drug use by history, 1983 to 1990.

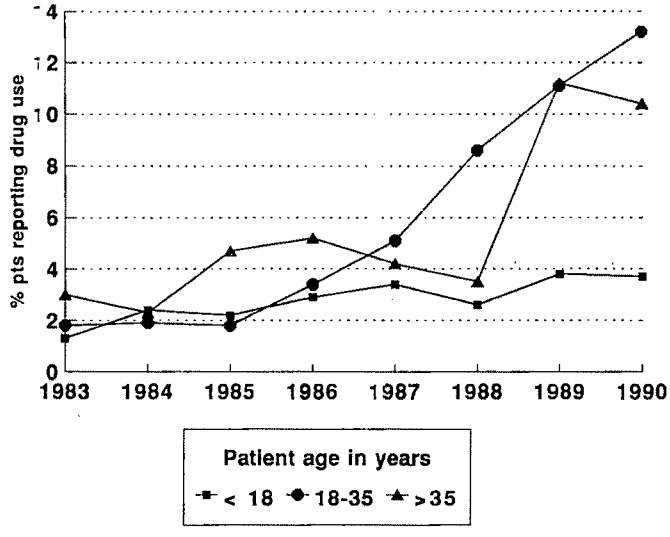

Fig. 2. Drug use in pregnancy by history, 1983 to 1990.

χ^2 analysis was applied, groups compared were checked to be matched for age, parity, hypertensive disease, diabetes mellitus, history of preterm delivery, tobacco use, alcohol use, and congenital anomalies.

Results

Between Jan. 1, 1983, and Dec. 31, 1990, a total of 25,453 patients were delivered at our institution. Excluded from the study were 1527 patients (6%) who had incomplete sets of data. Our analysis therefore is based on 23,926 patients (25.1% white, 70.1% black, and 4.8% of other races). The number of deliveries gradually increased from 2360 in 1983 to 3501 in 1990, an increase exclusively for black patients. Since 1984 several hospitals in our urban area closed and our institution absorbed an indigent black patient load.

The incidence of illicit drug use by patient's history is seen in Fig. 1. A history of illicit drug use during pregnancy was seen in 2% of patients in 1983 and increased to 10.9% in 1990. Increases for all racial groups accelerated around 1986. By 1990 the incidence was 12.2% for black women and 7.1% for white patients.

When illicit drug use was characterized by age group (Fig. 2), it could be seen that drug use in pregnancy is predominantly a problem for women >18 years old. The incidence of illicit drug use for teenagers ranged between 2.1% and 3.9% over the 8 years of study, while for women aged 18 to 35 the incidence increased from 1.8% in 1983 to 13.2% in 1990. In 1990 3.7% of teen-

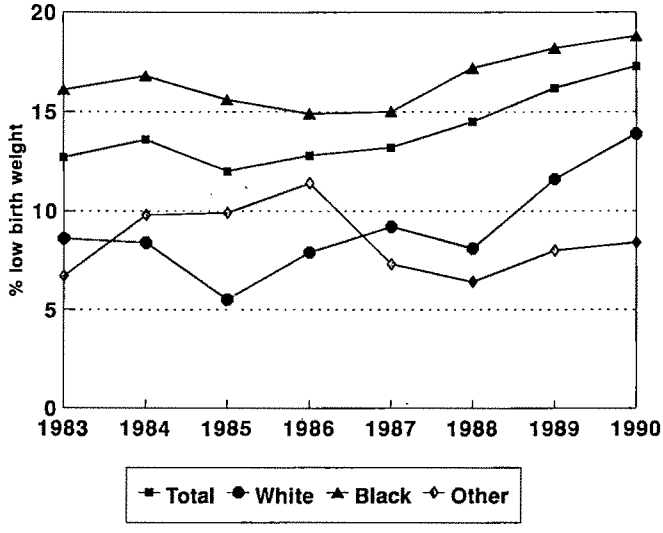

Fig. 3. Low birth weight, 1983 to 1990.

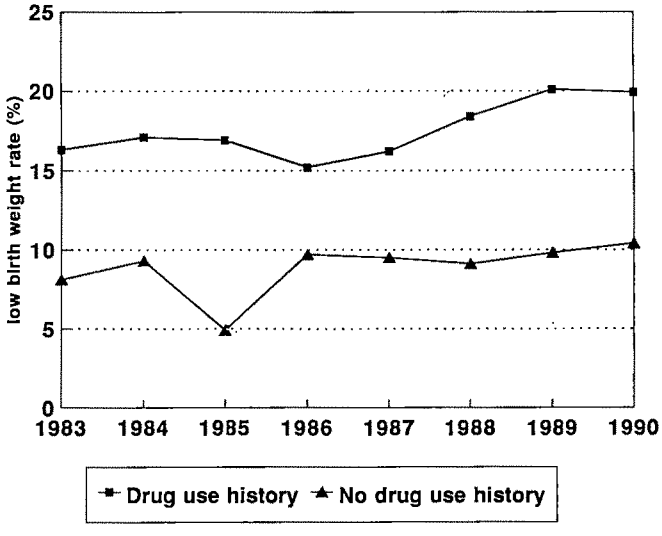

Fig. 4. Drug use and low birth weight, 1983 to 1990.

agers versus 13.2% of women aged 18 to 35 had a history of illicit drug use.

Low-birth-weight rates (Fig. 3) increased after 1987 for all races, reaching 17.3% by 1990, after a relatively stable rate from 12% to 13% from 1983 to 1986. The low-birth-weight rate increased from 5.5% in 1985 to 13.9% for white patients: for black patients it increased from a low of 14.9% in 1986 to 18.8% in 1990. These trends were not similar in all age groups. In fact, the low-birth-weight rate for parturients <18 years old declined from 18.7% in 1983 to 11.4% in 1990, while for patients aged 18 to 35 the rate increased from 12% to 18.1% in the same years.

The relationship between drug use and low birth weight is illustrated in Fig. 4. In each year from 1983 to 1990 the low-birth-weight rate was one and a half to two times higher for patients with a history of illicit drug use compared with patients without drug use. The differences were statistically significant ($p < 0.5$) for each year and for the total data set. No significant differences were found between the two groups in each year for each of the eight potential variables, mentioned under Material and methods. From 1986 to 1990 an increase was seen in low-birth-weight rate for drug users (15.2% to 19.9%) while patients without drug use maintained a rate around 9% to 10%.

Fig. 5 indicates the percentage of patients with five or fewer prenatal visits from 1983 to 1990. Since 1986 the percentage of patients with inadequate care started to rise rapidly, resulting in a fivefold increase for white

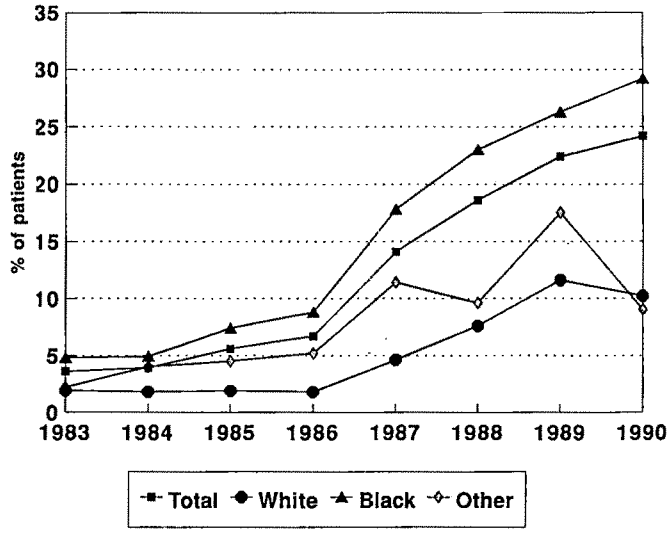

Fig. 5. Five or fewer prenatal visits, 1983 to 1990.

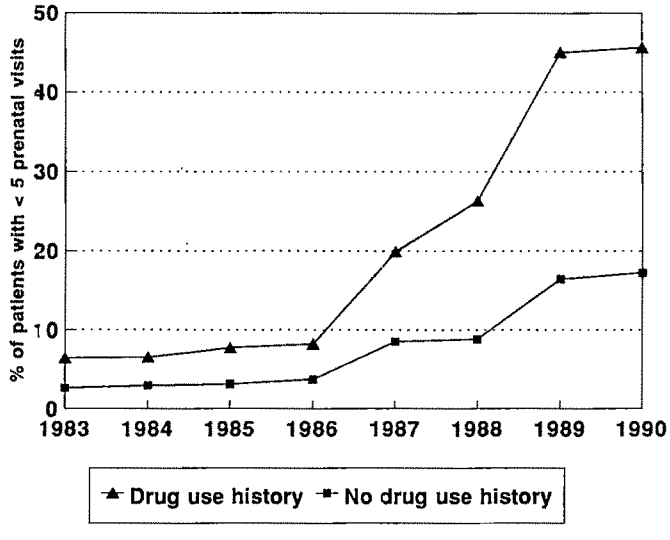

Fig. 6. Drug use and number of prenatal visits, 1983 to 1990.

patients and a sixfold increase for black patients, when 1983 is compared with 1990. Black patients had a two to three times higher likelihood of having five or fewer prenatal visits than did white patients (29.2% vs 10.2% in 1990). While the percentage of patients with five or fewer prenatal visits increased for patients in all groups, the largest increase was seen in women aged 18 to 35. The increase in this age group was from 3.6% in 1983 to 29.5% in 1990, while for teenagers the figures were 2.6% and 15.2% in the respective years.

An analysis of the relationships between drug use and adequacy or inadequacy of prenatal care is seen in Fig. 6. The percentage of patients with five or fewer prenatal visits was about double for patients with drug use between 1983 and 1986, and this gap widened from 1987 to 1990. By 1990, 45.6% of patients with drug use had five or fewer prenatal visits versus 17.2% of those without drug use. These differences were statistically significant for each year of analysis and for the total data set, whereas compared groups were matched for eight previously mentioned variables.

Preventable perinatal mortality (expressed as a percentage of perinatal deaths) rose over the 8-year period (Fig. 7). The largest increase was seen in black patients. By 1990, 42% of perinatal deaths were preventable (44% of black perinatal deaths versus 21% of white perinatal deaths). In Fig. 8 is the relationship shown between drug use and preventable perinatal mortality. Throughout the years of study patients with drug use had a two to three times higher incidence of prevent-

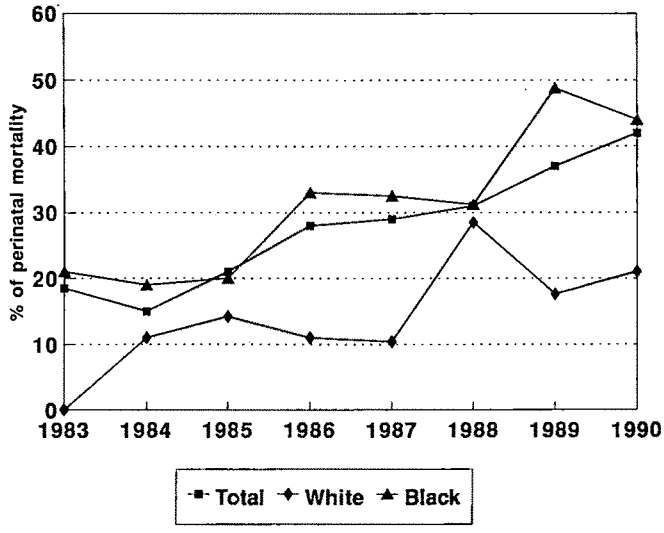

Fig. 7. Preventable perinatal mortality, 1983 to 1990.

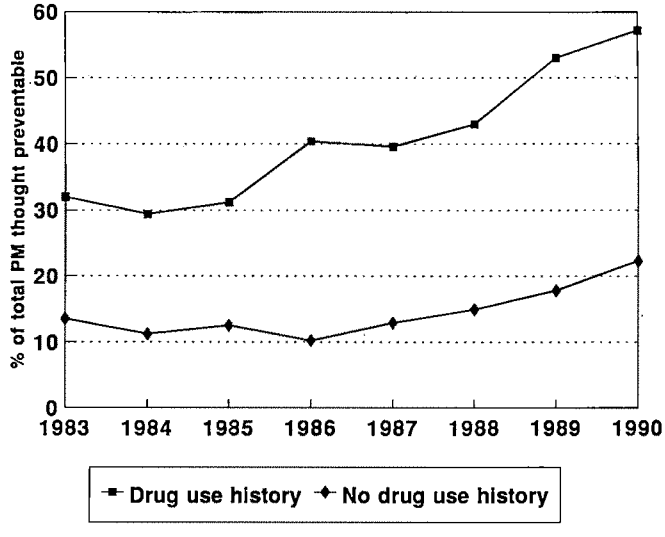

Fig. 8. Drug use and preventable perinatal mortality, 1983 to 1990.

able perinatal deaths than those without a history of drug use. The percentage of preventable perinatal deaths rose to 58.2% for drug users in 1990 versus 21.9% for patients without drug use. These differences were statistically significant for each year of analysis and the total data set, whereas compared groups were matched for eight previously mentioned variables.

The next analyses (Figs. 9, 10, and 11) separate the patients into three groups: group 1, drug use and five or fewer prenatal visits; group 2, drug use and more than five prenatal visits, group 3, no drug use and more than five prenatal visits. These groups were analyzed for their low-birth-weight rate, perinatal mortality, and preventable perinatal mortality.

The low-birth-weight rate (Fig. 9) in each year of analysis was the highest for drug users with five or fewer prenatal visits. In each year of analysis the incidence was about two to three times higher for group 1 (drug use, inadequate prenatal care) than for group 2 (drug use, adequate prenatal care). These differences were statistically significant for each year of analysis and for the total data set. No statistically significant differences were found between group 2 (drug use, adequate prenatal care) and group 3 (no drug use, adequate prenatal care), although low-birth-weight rates were 1% to 2% higher in the group with drug use. Obviously the most significant differences were seen between group 1 (drug use, inadequate prenatal care) and group 3 (no drug use, adequate prenatal care), as seen in 1990 with a 25.1% rate for group 1 versus 9.1% for group

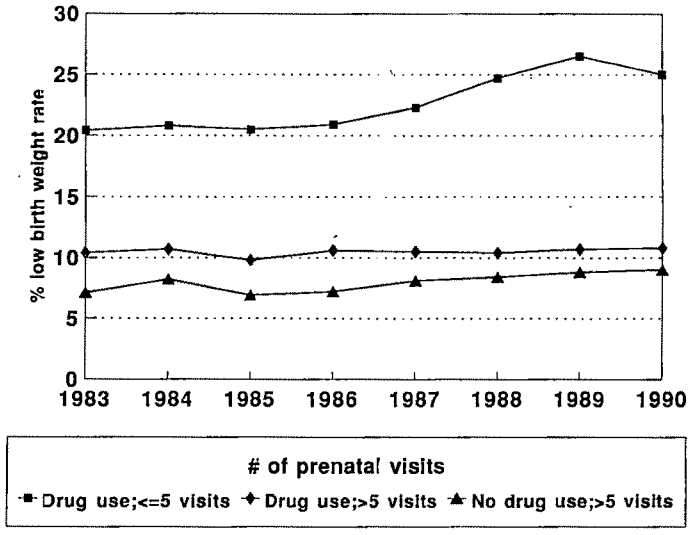

Fig. 9. Low birth weight, drug use, and prenatal care.

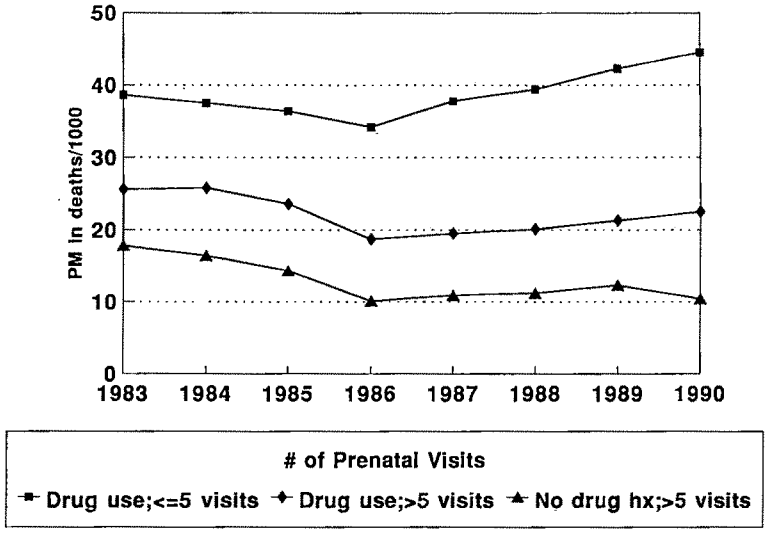

Fig. 10. Perinatal mortality, drug use, and prenatal care.

3. In all these comparisons groups were matched for the eight selected variables.

In a similar stratification the relationship between perinatal mortality, drug use, and number of prenatal visits is shown in Fig. 10. The perinatal mortality rate actually declined over the 8-year study period for patients with no drug use and more than five prenatal visits (from 17.9/1000 in 1985 to 10.6/1000 in 1990). Patients with drug use and more than five prenatal visits showed an initial decline from 1983 to 1986 and a slight increase from 1987 to 1990. Patients with a drug history and fewer than five visits had a two to four times higher incidence of perinatal mortality than patients without drug use and more than five prenatal visits. The differences between all groups were statistically significant, but the most pronounced differences were between group 1 with inadequate prenatal care and groups 2 and 3 with adequate prenatal care. Drug use had less effect (group 2 vs group 3) than adequacy of care (group 1 vs group 2). For example, in 1990 the perinatal mortality was 45.2 per 1000 for group 1, 22.4 per 1000 for group 2, and 10.6 per 1000 for group 3. In all these comparisons groups were matched for the eight selected variables.

Finally, in Fig. 11 the relationship is shown between preventable perinatal mortality, drug use, and number of prenatal visits. Throughout the years patients with drug use had a two to three times higher incidence of

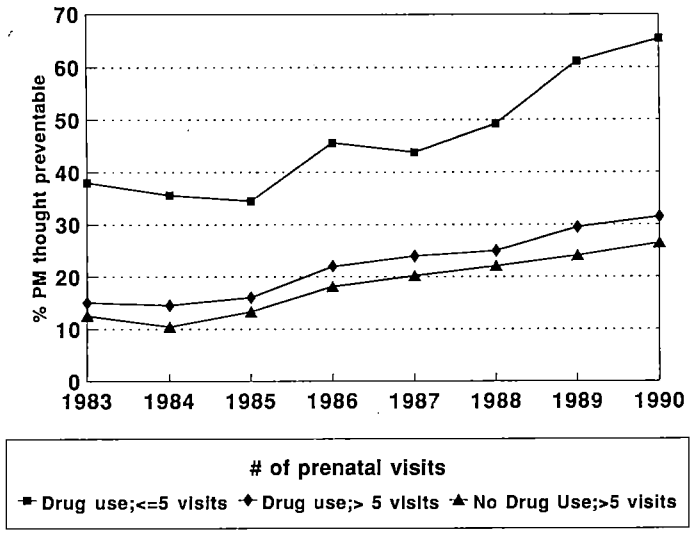

Fig. 11. Preventable perinatal mortality, drug use, and prenatal care.

preventable perinatal deaths if they had five or fewer prenatal visits when compared with patients with drug use and more than five prenatal visits. These differences were statically significant for each year and for the total data set. No significant differences were seen between groups 2 and 3 in each year and in the total data set. Significant differences were found in each year and in the total data set between group 1 versus group 2 or 3. In all comparisons groups were matched for eight selected variables. For example, in 1990 the percentage of preventable perinatal mortality was 65.4% for group 1, 31.2% for group 2, and 28.9% for group 3.

Comment

We conclude from these data that perinatal statistics worsened over the second half of the 1980s in one institution and urban community with persistent racial discrepancies in adverse outcome parameters. Crack cocaine arrived in Milwaukee in 1986. Illicit drug use and inadequacy of prenatal care increased significantly between 1986 and 1990, and a relationship between illicit drug use, inadequacy of prenatal care, and adverse perinatal outcome seems obvious. Illicit drug use during pregnancy increased, especially among women aged 18 to 35. This age group experiences inadequacy of prenatal care, perinatal mortality, and preventable perinatal mortality, as well as the most significant increases in low birth weight.

Our study made an effort to separate the perinatal outcome effects of inadequate prenatal care (arbitrarily defined as five or fewer visits) from the illicit drug use. Whereas drug use by itself had an adverse effect on low birth weight and perinatal mortality, the number of prenatal visits had a much greater influence on adverse outcome. Pregnant drug users with five or fewer prenatal visits had a two to four times higher incidence of preventable perinatal deaths, low birth weight, and perinatal mortality as compared with pregnant drug users with more than five prenatal visits.

Illicit drug use and addiction to alcohol in women have been strongly associated with low self-esteem, domestic abuse, a history of sexual abuse, and a chaotic life-style.[11, 12] We hypothesize that the number of prenatal visits for pregnant women with drug use is a marker of the degree of life-style chaos they experience and likely a marker of the severity of their drug use. As long as the patient is capable of obtaining adequate prenatal care while using drugs, immediate perinatal outcome is adversely affected on a limited scale. The patient is still reasonably "organizing" her life. The key ingredients are the organization and support systems that lead to an "adequate" number of prenatal visits. On the other hand, when prenatal care becomes clearly inadequate, extremely adverse effects are seen on immediate perinatal outcome. An important effect of illicit drug use in pregnancy is its influence on social behavior, incidence of sexually transmitted disease, inadequate nutrition, and compliance with prenatal care. In an urban setting existing socioeconomic circumstances often already place pregnancies at a higher risk for adverse outcome. While adverse socioeconomic circumstances cannot be resolved by medical interventions and root causes of illicit drug use among pregnant women (still rising in 1991 in many urban areas) are not affected by medical interventions, our data support the concept that outreach programs to actively recruit pregnant women with illicit drug use into prenatal care could obviate adverse pregnancy outcomes. These programs ought to be street corner and community based

and primarily address coping and chaos avoidance needs. The social chaos needs treatment first. The stage could then be set for adequate prenatal care and treatment of the addiction itself.

Discussion

DR. WASHINGTON C. HILL, Nashville, Tennessee. The effects of substance abuse or chemical dependency on the pregnant woman and her fetus have been reviewed in several publications.[1,2] We are about to lose, if we have not done so already, many of the gains we have made because of drug use during pregnancy. Maternal risks, depending on the substance, can result in death, stroke, sexually transmitted diseases, human immunodeficiency virus infection, and other serious maternal diseases, to mention only a few. The risks to the fetus or neonate as mentioned by Dr. Broekhuizen include spontaneous abortion, renal anomalies and other congenital anomalies, preterm birth, low birth weight, perinatal death, sudden infant death syndrome, and full neonatal intensive care nurseries among other problems. We have learned recently that the sperm may even act as a vector to transport cocaine into an ovum.[3] The question these authors tried to answer is, What is the underlying reason for adverse pregnancy outcome in patients who abuse substances? Why do these problems occur? Is it the drug use, inadequate prenatal care, or something else? Dr. Broekhuizen suggests that the patient's use of drugs, be they illicit (a term that I do not like) or nonillicit, causes a chaotic life-style that precludes the patient obtaining adequate prenatal care. He and his colleagues feel therefore that adequacy of prenatal care is a marker of "social chaos" and affects outcome *more than* the drug use itself. I am not sure that this is really the case. The social chaos (a term that I do like) is created by drug use and a number of other factors in these patients' lives. Social chaos is a marker for other ills in the patient's life and environment. Why patients do not come in for prenatal care is complex, whether they do or do not abuse substances.[1,2] Why do some patients seek care and others not? We have known for years that the lack of adequate prenatal care, whatever that is, correlates with poor or adverse perinatal outcome. This is not new. Intensive prenatal care improves perinatal outcome in the chemically dependent woman. Whether a patient who is abusing substances comes in for prenatal care is affected equally by her support system, how much in control of her life she really is, the environment where the prenatal care is given, and other factors. A patient, even though she may be abusing substances, who has a good support system at home, who is in some control, and who is made to feel accepted at her prenatal care environment (our responsibility) will obtain and continue to seek prenatal care. The patient who has little or no support system, who is in poor control of her life, and whose prenatal care environment is not receptive to taking care of her either will not obtain prenatal care or will leave it. By the way putting the substance-abusing pregnant woman in jail, as has been proposed by some and abhorred by others, is not considered being receptive.

I believe it is not simply the number of prenatal visits, whether four, five, six, seven, or eight, that determines the perinatal outcome but these other factors as well. The number of prenatal visits certainly influences adverse outcome, but what we really need to get at is what influences the number of prenatal visits and what we need to do to increase that number. Dr. Broekhuizen is correct in his diagnosis, but we need to go further if we are to treat the problem effectively. Culturally sensitive outreach programs that actively recruit pregnant women into prenatal care will definitely obviate adverse pregnancy outcome. This article suggests, although slightly, that this is all we need to do. It really isn't! What is sorely needed are more adequate comprehensive prenatal treatment programs for these patients.[2] Clearly, there are all too few treatment centers and only a rare residential program for the drug-dependent pregnant woman. A successful approach to combat this problem must include unique prevention, treatment, and research efforts. The authors have attempted to tackle an elusive problem that is facing all of us who practice. Although there may be problems with the design of their study, they have given us food for thought, on which we need to go further.

I have the following questions for Dr. Broekhuizen:

1. Why use the term *illicit drug use?* Use of this term suggests that drugs which are not illegal are okay

to use during pregnancy—a point, however, I know Dr. Broekhuizen is not making.
2. What is the desired number of prenatal visits for optimal perinatal outcome? How did you come up with five?
3. Are there other reasons for the worsening perinatal statistics between 1983 and 1990?
4. What are the reasons and the possible cures for the disappointing persistent racial discrepancies?
5. What data support stating that crack cocaine arrived in Milwaukee in 1986 and illicict drug use increased significantly between 1986 and 1990? There is a National Institute on Drug Abuse report of a decline in the use of illicit drugs by women of childbearing age.[4]
6. There is a definite relationship between drug use, inadequate prenatal care, and adverse perinatal outcome. Where do resources, the degree of social support, and other factors fit into this formula?
7. Why did you exclude those who used alcohol and did you really do so?
8. Finally, and I know you have a quick answer for this one, what is "adequate prenatal care"?

Dr. Sidney F. Bottoms, Detroit, Michigan. Dr. Broekhuizen and his colleagues have presented a very provocative article describing the interactions of drug abuse, inadequate prenatal care, and adverse perinatal outcomes. On the basis of their analysis, they conclude that adequacy of prenatal care is a marker of "social chaos" and that this affects outcome more than drug use itself. Although this conclusion may be correct, I have difficulty in accepting it on the basis of the data and analysis presented thus far. In my discussion I'll first cover a few technical considerations. After that, I'll address some practical issues and then present the authors with specific questions.

It seems that physicians often have the same warm feeling about statisticians that they do about attorneys. Sometimes, however, it is important to overcome our anxieties and seek the services of a professional statistician. I would like to cite a few of the reasons why I would recommend that the authors obtain a statistical consultation. Although the first sentence of the abstract indicates that trends in drug use were analyzed, all statistical comparisons were made between groups within a given year. An analysis of trends, of course, requires statistical comparison between years. There is also no information about how large the denominaotrs are for calculating rates. This leaves both the statistical reviewer and the reader at a loss to determine the degree to which these rates are subject to variation. For example, I believe that the authors would agree that a rate of 20% based on one out of five patients would be interpreted quite differently than a rate of 20% based on 100 out of 500 patients. Typically, large epidemiologic studies either have used a minimum size for denominators to calculate rates, have reported the actual size of the groups, or have presented confidence intervals to facilitate accurate interpretation of the data. There is also a multiple comparison problem; there are at lease 88 independent comparisons at $p < 0.05$. You would expect that 5% of the 88 comparisons or a total of four "significant" results would actually be due to chance alone (statistical "flukes"). A more sophisticated statistical model, a hierarchical design, or a lower p value considered significant is frequently used by statisticians to minimize this type of problem.

There are also several practical issues in interpreting the data that must be considered. The authors have compared perinatal mortality rates in a control population with adequate prenatal care, drug abusers with adequate prenatal care, and drug abusers without adequate prenatal care. The last of these groups had a higher perinatal mortality rate. They interpret this to mean that the adequacy of prenatal care is a marker for "social chaos" and that it affects outcome more than drug use itself. The authors failed to provide any information about drug-free patients with inadequate prenatal care. Without this comparison group, it is impossible to determine whether the authors' conclusion is warranted. Often, this drug-free group without adequate prenatal care has many pregnant adolescents who, in spite of their lack of prenatal care, seem to fair better than drug abusers. To draw their conclusion, the authors have implied that drug abusers who receive adequate prenatal care are otherwise comparable to drug abusers with inadequate care. Typically, this is not the case. Substance abusers who receive adequate prenatal care are likely to be lighter users, to marijuana rather than crack cocaine or heroin, and to have decreased drug use during pregnancy. Although I could cite references for this point, I doubt that anyone would argue that a woman "high" on cocaine or heroin is less likely to make or keep an appointment for prenatal care than one in complete command of her senses.

Finally, I have three specific questions for the authors. First, do the authors have any data reporting outcome according to the specific type of drug abuse? Information on this subject would be helpful in determining whether drug abusers with and without prenatal care were comparable. The second question is in regard to whether the authors have made any comparisons controlling for such important factors as socioeconomic status, race, alcohol abuse, or smoking. Known associations of substance abuse and inadequate prenatal care with one or more of these factors could account for the effects ascribed by the authors to "social chaos." Finally, do the authors have any information regarding perinatal outcome among drug-free women with inadequate prenatal care?

Dr. Pedro A. Poma, Melrose Park, Illinois. We know that for every patient we find who has a history of drug

use there are >10 women who may be found by routine screening. At what prevalence level in the community do you recommend we must do routine screening?

PRESIDENT YOUNGBLOOD. I would just add my own comment. In 1983, our low-birth-weight rate was about 15%. We watched it go down until about 1986 or 1987 to 11%, and it has been on the rise since to 15%.

DR. BROEKHUIZEN (Closing). I thank both Dr. Hill and Dr. Bottoms for their thoughtful comments and criticisms; I knew that there were some valid criticisms of this study.

Dr. Hill suggested that our conclusion was that simply the number of prenatal visits affected outcome. If that was the conclusion, I probably ought to rewrite the Comment section of the article, because that would be an unfortunate conclusion.

In fact, I feel that our data support Dr. Hill's belief that the social support system and the support within the prenatal care environment are the first two ingredients for prenatal care for a disadvantaged population. I thought we concluded the same.

The perinatal statistics for patients without drug use but with inadequate prenatal care, and I can answer Dr. Bottoms' third question right here, are still unacceptably high in our institution. If we had included them in the statistics, and I accept the criticism that we should have, they were better than in the group with drug use and inadequate prenatal care but worse than in the group with drug use and adequate prenatal care.

Our point is that drug use is associated with even more social chaos than in those patients with just inadequate prenatal care, and the social chaos needs to be addressed.

Another of Dr. Hill's questions pertained to illicit drug use as a term. I do not like that term either. We were asked to do the study to come up with some rationale for funding, and we used this data base for birth certificate information. The subcategory that is used for the birth certificate in Wisconsin is "illicit" drug use and we were tied to that particular category.

Five prenatal visits as a cutoff and what is adequate prenatal care—this was done initially because the average number of prenatal visits in all the years was 9.9, so we thought we would take half. When we analyzed differences between groups at one, two, three, four, and five prenatal visits, we started to lose any statistical significance at about five. So five was the highest number at which we could find statistical differences.

Are there other reasons for worsening perinatal statistics? Increasing unemployment, crime, poor housing, less-accessible Medicaid programs since 1983 in our community, health maintenance organization–run Medicaid programs, and in the last year a provider shortage have contributed to these statistics.

Reasons and cures for persistent racial discrepancies—another one of Dr. Hill's questions—socioeconomic differences, still very much along racial and economic lines. This applies as well to access to medical care. These are the root problems and they are compounded by lack of cultural sensitivity in many medical care settings. That's my diagnosis. I think we all have to come up with the cure.

Data to support that crack cocaine hit Milwaukee in 1986? Although our police department's performance is somewhat in question lately, criminal statistics, halfway houses, and drug rehabilitation settings provided that information.

Alcohol, did we really include or exclude? We actually used alcohol and tobacco use as control variables. The same is true for race and age. So, and this might answer Dr. Bottoms' second question to some extent, we matched the patients for age, race, and about eight other variables in all comparisons. We might want to make that a little bit more clear in the final version of the article.

What is adequate prenatal care? Dr. Hill asked for a quick answer. I'll try. A minimum of pure medical content can be defined, but I think that in most cases it will have to be individualized and dependent on the health, knowledge, and life-style of individual patients.

I do know that patients with adverse pregnancy outcome in my institution need a lot more care than just medically defined care, which would be sufficient for my suburban neighbor, and that's about the best way I can answer that question.

Dr. Bottoms, I have to accept having been a somewhat poor student of some of your statistical courses. I accept your criticism regarding the reporting of the statistics. Now, with several hardware and software transitions that we experienced in our institution over the last 8 years and actually a move of the whole institution, it was impossible to do multivariate analysis. I accept some weaknesses in our statistical approach. Nevertheless, I believe that they do not interfere with the validity of our conclusions.

Dr. Poma, at what prevalence rate in the community do I recommend routine screening? I don't have an answer to that. I really think you have to define that in your own community.

And last, in answer to Dr. Youngblood's comment, I think one of the more tragic things that permeates this study may not be the question of drug use versus inadequate prenatal care. The more tragic feature may be the persistence of racial discrepancies and the worsening of perinatal statistics over the last 4 or 5 years in our urban environment.

Eclampsia

VII. Pregnancy outcome after eclampsia and long-term prognosis

Baha M. Sibai, MD, Cem Sarinoglu, MD, and Brian M. Mercer, MD
Memphis, Tennessee

OBJECTIVES: Our goal was to report pregnancy outcome and long-term prognosis after eclampsia.
STUDY DESIGN: Women whose pregnancies were managed at the E.H. Crump Women's Hospital between August 1977 and April 1989 were studied. A total of 223 women with eclampsia underwent follow-up for an average of 7.2 years. Thirteen had preexisting hypertension and 210 were normotensive (31 were multiparous and 179 were nulliparous).
RESULTS: Among these women 23 who were multiparous and 159 who were nulliparous had 366 subsequent pregnancies: 22% of pregnancies were complicated by preeclampsia, 1.9% by eclampsia, and 2.5% by abruptio placentae; 2.7% resulted in perinatal death. Within the nulliparous group, women who had eclampsia before 37 weeks' gestation in the index pregnancy had significantly higher incidences of preeclampsia and poor perinatal outcome in subsequent pregnancies as compared with those who had eclampsia at ≥37 weeks' gestation; the highest incidence of obstetric complications occurred in those having eclampsia at ≤30 weeks. Twenty of the 210 normotensive women (9.5%) had chronic hypertension on follow-up; the highest incidence (17.9%) being in those with eclampsia at ≤30 weeks and the lowest incidence (4.8%) in those having eclampsia at ≥37 weeks. Women with eclampsia who had preeclampsia in subsequent pregnancies had a higher incidence of chronic hypertension as compared with those who were normotensive in subsequent pregnancies (25% vs 2%, $p < 0.0001$). Long-term maternal complications included dialysis required in one patient and one case of cardiomyopathy in women with chronic hypertension; there was one maternal death in a woman with chronic hypertension. None of the women had evidence of neurologic deficit or seizures during follow-up.
CONCLUSIONS: These findings should be used in counseling women who have had eclampsia and are considering future pregnancies. (Am J Obstet Gynecol 1992;166:1757-63.)

Key words: Eclampsia, recurrence, remote prognosis

Eclampsia is becoming a rare complication of pregnancy in the Western world.[1,2] However, it continues to be a major health problem in developing countries,[3,4] as well as among young indigent patients in the United States.[5,6] Pregnancies complicated by eclampsia are still associated with increased perinatal mortality and morbidity.[7] In addition, such pregnancies are usually also associated with increased maternal morbidity: hemolysis, pulmonary edema, disseminated intravascular coagulopathy, cerebral injury, and acute renal failure.[3,7]

The development of eclampsia, particularly when associated with poor maternal-perinatal outcome, is a frightening experience for both the patient and her family members. As a result, the managing physician must be prepared to answer questions regarding outcome in future pregnancies, as well as any potential long-term residual damage from eclampsia and/or its complications. The purpose of this study is to report subsequent pregnancy outcome and remote maternal prognosis of 223 eclamptic women.

Material and methods

E.H. Crump Women's Hospital and Perinatal Center in Memphis serves as a tertiary referral center for an area that includes five states: Tennessee, Arkansas, Mississippi, Missouri, and Kentucky. During the time period from August 1977 to April 1989, 254 of the pregnancies managed at this center were complicated by eclampsia. The diagnosis, management, and maternal-perinatal outcome of these patients were previously described.[5] One patient died during the acute eclamptic episode, and one patient died of massive pulmonary embolism at about 9 weeks post partum after admission to a local hospital. This latter patient had tricuspid atresia with secondary pulmonary hypertension.

Twenty-nine of the 252 surviving patients either had inadequate medical follow-up data or were lost to fol-

low-up. The remaining 223 patients had adequate medical follow-up data for at least 2 years after eclampsia. These latter patients served as the study population for this report.

Early follow-up (first 6 weeks) after delivery was done at our obstetric clinics, whereas subsequent follow-up data were obtained from our clinics, local physicians, local health departments, and local hospital records. In the majority of cases the patients were seen and followed up by B.M.S. Maternal evaluation included an interval history with special emphasis on history of convulsions and/or neurologic deficit, use of anticonvulsive and/or antihypertensive medications, and future pregnancy outcome. Outcome in subsequent pregnancies was reviewed with regard to incidences of preeclampsia-eclampsia, abruptio placentae, and perinatal outcome. Only pregnancies delivered beyond the first trimester were included in the analysis.

All data pertaining to blood pressure measurements during subsequent physical examinations and/or pregnancy were obtained. The diagnosis of chronic hypertension was based on the presence of documented hypertension (either before the index pregnancy or on follow-up) for which the patient received antihypertensive therapy. This diagnosis was usually made when the patient had persistent elevations of diastolic pressure of at least 90 mm Hg on two occasions at least 6 months apart.

Data analysis was performed with X^2 or Fisher's exact test and odds ratios. A p value of <0.05 was considered significant.

Results

Thirteen women had preexisting chronic hypertension and/or renal disease before the onset of eclampsia. Eleven were black and two were white. Seven were multiparous and six were nulliparous. The mean age of onset of eclampsia in these patients was 25.2 years (range 14 to 36 years), and the mean duration of follow-up was 7.2 years (range 3 to 13 years).

Six of the 13 women had no subsequent pregnancies, and the other 7 had a total of 13 subsequent pregnancies. Of these 13 pregnancies 7 (53.8%) were complicated by severe preeclampsia, 5 (38.5%) were complicated by mild hypertension, and one was normotensive. Four (30.8%) of the 13 resulted in perinatal death, four were complicated by fetal growth retardation (<10th percentile for gestational age), and one (7.7%) was complicated by abruptio placentae.

The mean maternal age at time of last follow-up in these 13 women was 32.4 years (range 19 to 45 years). In one patient hypertensive cardiomyopathy developed after 3 years of follow-up, and progressive renal failure necessitating dialysis developed 6 months after eclampsia in one patient with biopsy-proved glomerulosclerosis. This patient is still undergoing dialysis after 5 years of follow-up. One additional patient died of cardiovascular complications after 13 years of follow-up. In addition, none of the surviving women had evidence of neurologic deficit or seizures on follow-up.

A total of 210 women were normotensive at the time of onset of eclampsia. Forty-one (19.5%) were white, 168 (80%) were black, and one was Asian. Thirty-one (14.8%) were para ≥1 and 179 (85.2%) were nulliparous. The mean age at onset of eclampsia in these patients was 18.0 years (range 11 to 34 years), and the mean duration of follow-up was 7.2 years (range 2 to 13 years).

Twenty nulliparous women had no subsequent pregnancies, and the other 159 had a total of 334 subsequent pregnancies. Eight multiparous women had no future pregnancies, and the other 23 had a total of 32 subsequent pregnancies. Table I summarizes the pregnancy outcome in these women according to parity. The overall incidence of preeclampsia-eclampsia in subsequent pregnancies was 23.8%. There was no difference

in this incidence between women who had eclampsia as nullipara and those who were multipara; however, all cases of repeat eclampsia occurred in the nulliparous group. In addition, all cases of abruptio placentae and perinatal deaths occurred in the nulliparous group.

Table II compares outcome in subsequent pregnancies in nulliparous women according to gestational age at the time of onset of eclampsia in the index pregnancy. The women who had eclampsia before 37 weeks' gestation had significantly higher incidences of both mild and severe preeclampsia in subsequent pregnancies as compared with women who had eclampsia at ≥37 weeks' gestation. In addition, this group of women had a significantly higher incidence of poor perinatal outcome in subsequent pregnancies. Moreover, women who had eclampsia at ≤30 weeks' gestation had the highest incidence of preeclampsia and the worst perinatal outcome in subsequent pregnancies.

The mean maternal age at the time of last follow-up in the 210 women who were normotensive at the time of eclampsia was 25.2 years (range 17 to 43 years). In 3 of the 31 multiparous women (9.7%) and 17 of the 179 nulliparous women (9.5%) chronic hypertension developed during follow-up. The overall incidence of chronic hypertension was 9.5%.

For the 179 nulliparous women, the data were subsequently analyzed according to gestational age at time of onset of eclampsia in the index pregnancy. Twenty-eight of these women had eclampsia at ≤30 weeks, 68 at 31 to 36 weeks, and 83 at ≥37 weeks. The average durations of follow-up among these three groups were 7.8, 7.0, and 7.3 years, respectively. Fig. 1 describes the incidence of chronic hypertension among the various groups. Within this group, women who had eclampsia at ≤30 weeks' gestation had a significantly higher incidence of chronic hypertension as compared with those who had eclampsia at ≥37 weeks ($p < 0.04$, odds ratio 4.3:1). In addition, women who had eclampsia at 31 to 36 weeks' gestation had a higher incidence of chronic hypertension as compared with those who had eclampsia at ≥37 weeks. However, this difference did not reach statistical significance ($p = 0.11$, odds ratio 2.6:1).

For the nulliparous women who had subsequent pregnancies ($n = 159$), the data regarding development of chronic hypertension were analyzed according to outcome in subsequent pregnancies. In 16 (10%) of these women chronic hypertension developed on follow-up. Within this group of women, 103 had normotensive subsequent pregnancies and 56 had at least one subsequent pregnancy that was complicated by preeclampsia. In 2 of the 103 women with normotensive subsequent pregnancies (2%), hypertension developed, whereas hypertension developed in 14 (25%) of the 56 women with subsequent preeclampsia ($p < 0.0001$, odds ratio: 22.1).

There were no maternal complications on follow-up in these patients, and none of the women had evidence of neurologic deficit or seizures on follow-up.

Comment

The findings of this study indicate that women in whom eclampsia develops are at increased risk of preeclampsia-eclampsia and abruptio placentae in subsequent pregnancies. The risks were particularly increased in those women who had preexisting chronic hypertension before the onset of eclampsia. In these women the risk of severe preeclampsia in subsequent

*Follow-up in only one subsequent pregnancy.
†Data not available.

pregnancies was 53.8%, whereas the risk of abruptio placentae was 7.7%. In addition, these women had an increased rate of perinatal death (30.8%) and an increased incidence of fetal growth retardation (30.8%) in subsequent pregnancies. Thus they should be informed of the high likelihood of severe preeclampsia and poor perinatal outcome in subsequent pregnancies. Moreover, such women should be informed of the increased long-term maternal morbidity and counseled regarding close medical follow-up.

For the women without chronic hypertension before the onset of eclampsia, the risk of preeclampsia in subsequent pregnancies was 21.9%, the risk of eclampsia was 1.9%, and the risk of abruptio placentae was 2.5%. The risks were similar whether the patient had eclampsia when nulliparous or multiparous. However, the incidence of these obstetric complications was more than threefold higher than the expected incidence for similar complications in the general obstetric population at this hospital. In addition, within the group who had eclampsia when nulliparous, the risk of obstetric complications in subsequent pregnancies was related to the time of onset of eclampsia (Table II). Women who had eclampsia at ≤30 weeks' gestation had increased rates of severe preeclampsia, abruptio placentae, preterm birth, and perinatal death in their subsequent pregnancies, whereas women who had eclampsia at ≥37 weeks' gestation had only an increased rate of eclampsia

(2.4%) in their subsequent pregnancies. These findings support our previous observations in a similar study[8] and should be used in counseling those women who are considering future pregnancies.

During the past 20 years there have been three studies describing pregnancy outcomes after eclampsia.[9-11] The findings of these studies, as well as those of the current study, are summarized in Table III. It is important to note that the findings of this study are almost identical to those reported by Chesley.[9] The other two studies reported from Mexico and Nigeria found higher incidences of preeclampsia-eclampsia, preterm birth, and fetal growth retardation as compared with our findings. These differences may be related to differences in populations studied, as well as to management used.

The long-term effects of eclampsia on maternal blood pressure have been extensively studied by Chesley,[9] who concluded that eclampsia does not lead to chronic hypertension later in life. The results of this study show that women without evidence of chronic hypertension before eclampsia have a 9.5% incidence of chronic hypertension on follow-up. The incidence was similar whether the patient had eclampsia when nulliparous or when multiparous. In addition, this incidence was similar to the respective incidence in the general female population (age groups 25 to 34 years).[8] On the other hand, the incidence of chronic hypertension was significantly higher in those who had eclampsia at ≤30 weeks' gestation (17.9%) than in those who had eclampsia at ≥37 weeks' gestation (4.8%). Moreover, in women who had subsequent pregnancies, the incidence of chronic hypertension was significantly higher in those who had subsequent pregnancies complicated by preeclampsia (25%) than in those who had normotensive subsequent pregnancies (2%). These findings may be useful regarding the counseling of these women about future medical follow-up.

None of the surviving women had evidence of neurologic deficit or seizures on follow-up from 2 to 13 years. These findings are in disagreement with the conclusions of Sexton,[12] who suggested an association between eclampsia and future development of epilepsy. This difference might reflect differences in short-term management of eclampsia and its complications.

Discussion

DR. NORMAN F. GANT, Dallas, Texas. I enjoyed the well-prepared study by Sibai et al. This report continues the saga of the management of eclampsia by this group of investigators in Memphis and is an original study of the outcome in 223 patients with eclampsia. The outcome follow-up ranged from 2 to >13 years.

The study design included a separation of patients into those who had chronic hypertension at the time of eclamptic seizures; there were 13 such patients. There were 210 patients who had been normotensive before eclamptic seizure. The outcome, with respect to subsequent pregnancies, development of hypertension, neurologic complications, and other long-term consequences, was then assessed with respect to those patients who had chronic hypertension at the time of seizure and the outcomes that were observed in those women who had been normotensive before eclamptic seizure. Additionally, the patients were further divided into nulliparous patients and multiparous patients at the time of eclamptic seizure. Finally, those patients who were nulliparous at the time of seizure were then further divided into the time of onset of the eclamptic seizure (i.e., <30 weeks, between 30 and 37 weeks, and >37 weeks). Sibai et al. then compared their results with three previously published, similar studies of outcome in patients with eclampsia.

In summary, Dr. Sibai observed that those women who had chronic hypertension at the time of eclamptic seizure fared very poorly. There was one death in this group and there was a high incidence of repeat severe hypertension in subsequent pregnancies. There were, interestingly enough, no neurologic sequelae, but there was one renal failure and one severe cardiomyopathy.

With respect to those patients who had been normotensive before eclamptic seizure, the outcome, as previously mentioned, was separated into those women who were nulliparous and multiparous at the time.

There appeared to be no difference between nulliparous and multiparous women in long-term outcome variables, at least for the duration of the study. In those women who had been nulliparous at the time of seizure, there was a significantly higher incidence of later hypertension and recurrent hypertension in those women who had eclamptic seizure at ≤30 weeks, compared with those who had eclamptic seizure at 30 to 37 weeks and those who had seizure after 37 weeks. Finally, there was approximately a 2% recurrence of eclampsia in each of the three groups of women separated by gestational age at the time of previous eclamptic seizure.

The results of this interesting study compared most favorably with those obtained by Chesley in his now-famous long-term follow-ups cited by the authors in their report.

I have only two questions for the authors. First, in spite of the tremendously worse outcome variables in the patients with chronic hypertension at the time of eclamptic seizure, I noted that there were no repeat eclamptic seizures in this group of individuals. Was this because the numbers were too few, or was this because these patients underwent close follow-up in subsequent pregnancies? Finally, I am amazed at the number of cases of eclampsia that Sibai et al. continue to accrue in Memphis. I wonder if there has been a decrease in the incidence of eclampsia in their population since they instituted an increased dosage of magnesium sulfate to 2 gm/hr as prophylaxis against eclamptic seizures?

Dr. Jennifer R. Niebyl, Iowa City, Iowa. Dr. Sibai has taught us a great deal about eclampsia, and this is the seventh in a series of articles describing this disorder. He has previously reviewed the maternal and perinatal outcomes in the index pregnancies of 254 patients with eclampsia.[1] He now presents long-term follow-up of both maternal status and fetal outcome in subsequent pregnancies of 223 of these individuals. They have had follow-up for a mean of 7.2 years with a range of 2 to 13 years.

Of note is the 1.9% recurrence rate of eclampsia, in a total of seven patients. Sibai et al.[2] previously reported that 31% of cases of eclampsia are not preventable with standard prenatal care. My questions for Dr. Sibai are: Did the physicians make any adjustments in prenatal surveillance in subsequent pregnancies? Did these patients with previous eclampsia make more frequent visits in their subsequent pregnancies? Was there more aggressive use of magnesium sulfate therapy in the subsequent pregnancies or was there longer postpartum observation? What are your recommendations for prenatal care in women at increased risk for eclampsia?

Bryans et al.[3] carried out follow-up of women who had eclampsia and were treated at the Medical College of Georgia; they found no increase in subsequent chronic hypertension in these patients above that expected in the general population. Chesley et al.[4] monitored women with eclampsia at the Margaret Hague Hospital in New Jersey from 1931 to 1951, and they also concluded that eclampsia does not cause hypertension. This article reported that the risk of chronic hypertension is increased in this population, especially in those who had eclampsia before 30 weeks. Dr. Sibai, what is the risk of subsequent essential hypertension in your population without eclampsia? How great is the increased risk over the background risk? Why is this different from previous studies?

I look forward to an article reporting that resources are available and access to prenatal care is such that eclampsia has finally been eliminated in Tennessee and adjacent states.

Dr. James N. Martin, Jr., Jackson, Mississippi. I have two questions for you regarding this excellent report. Do you think that the occurrence of preeclampsia earlier than 30 weeks in gestation is a marker of underlying chronic hypertensive disease in the first place? Is it not the horse rather than the cart?

Second, along the lines of Dr. Niebyl's comment and on the basis of your work with low-dose aspirin and calcium supplementation, do you think that modification of prenatal care for these special patients should include one or both of those substances or something else?

Dr. Steven E. Calvin, Minneapolis, Minnesota. I have a brief question. The assay methods for—and the understanding of—antiphospholipid antibodies have changed over the course of this study. Do you have any information about the presence of antiphospholipid antibodies, especially in the subset of <30 weeks?

Dr. Allan G. Charles, Chicago, Illinois. Considering the wide geographic area covered and the difficulties in follow-up of indigent patients, I wonder how Dr. Sibai has been able to monitor such a large number of patients for such a long period of time.

Dr. Sibai (Closing). I thank Dr. Gant and Dr. Niebyl for their kind remarks. Regarding the comments of Dr. Gant as to why we didn't see eclampsia in the 13 pregnancies in women who had previous chronic hypertension, there are probably two reasons.

First, the numbers are too small, only 13 pregnancies. Second, women who have chronic hypertension tend to have more close and intensive follow-up, and once (superimposed) preeclampsia develops, we become

very aggressive regarding indications to deliver them. This would probably explain why we didn't see it.

Regarding magnesium sulfate, I'm also surprised that we continue to see these cases of eclampsia because I would think the number would decrease. In Memphis, this hasn't changed in >40 years. We are still seeing the same problem. So the effort has to be directed to preventing preeclampsia, which is the first step before the onset of eclampsia. There is no doubt that after we increased magnesium sulfate to 2 gm/hr (described in my original report in 1981) the incidence of convulsions in women with preeclampsia who were receiving magnesium sulfate was about 1 in 125 women. Since 1985, when we started the 6 gm loading dose and 2 gm/hr, the incidence has fallen to about 1 in 400.

Dr. Niebyl brought up a very interesting point regarding recurrence. Is there any way we could have prevented recurrence in these seven nulliparous patients? Looking at the data in these patients, I guess better care could have prevented recurrence in about three of those seven.

For example, one of the patients had the first onset of eclampsia at 33 weeks. The second one had prenatal care for two visits. The third time she came, she had a blood pressure of 240/140 mm Hg and proteinuria (4+). The problem was she was only 18 weeks' gestation, and the physicians that consulted didn't really think of preeclampsia. So they treated the high blood pressure and did everything possible, thinking it would be renal disease. Magnesium sulfate was not used, and then eclampsia developed at that early stage. This patient had follow-up and she is still normotensive.

Few other patients have eclampsia develop as late-onset. They have preeclampsia. They receive magnesium sulfate, and then 3 or 4 days later eclampsia develops. It's very difficult to see how we could have prevented these cases, and we cannot blame the physicians who were taking care of them.

Interestingly, one other case was followed up at a local hospital. She had late-onset eclampsia the first time. The second time preeclampsia developed. She was given magnesium sulfate for 12 hours. Then magnesium sulfate was stopped, and eclampsia developed 19 hours later. This patient probably should have received magnesium sulfate ≥24 hours.

I think this corresponds with the comments of Dr. Martin. Maybe what we need to do more than anything is to prevent preeclampsia, because almost all of these women have preeclampsia. Currently, I don't know whether aspirin or calcium is going to prevent preeclampsia. There are trials going on at the present time, so we have to await the results.

To date the trials with calcium have not produced any benefit regarding preeclampsia. They have shown some benefit regarding the incidence of pregnancy-induced hypertension.

Dr. Niebyl mentioned the 9.5% incidence of chronic hypertension as being increased. I don't think this 9.5% incidence is slightly increased. If we look at the incidence using vital statistics for black patients in the United States, this incidence corresponds to that for the age group 25 to 34 years. The average age group in this follow-up was 25, so it seems our patients fit in the upper limit.

This agrees with the important point, which is that I don't believe eclampsia causes hypertension. I think what we are seeing is that eclampsia is like gestational diabetes. Women in whom severe preeclampsia or eclampsia develops early in gestation are at increased risk to have repeated episodes later on. Actually, these women might have had previously silent or underlying chronic hypertension or renal disease. In patients with either severe preeclampsia or eclampsia at <30 weeks, there is no doubt that a very large percentage of these women will have chronic hypertension or some form of renal disease. I don't think it has anything to do with eclampsia. It just became manifest during pregnancy.

There was a question about antiphospholipid antibodies. We have measured antiphospholipid antibodies in >200 women, particularly those who have the disease very early; I have yet to see a single positive test result. I personally do not think that there is a strong association the way it was previously stated in the literature. I think women who have antiphospholipid antibodies tend to have a syndrome similar to preeclampsia, but the reverse is not true.

Finally, in response to the question about close follow-up, you would be amazed, when you have a close relationship with these patients and you have been keeping in touch with them and their children, that they are very compliant with follow-up. Also, they were very good in bringing their children for follow-up, particularly those who were delivered of preterm babies. So, no, I'm not surprised that we were able to do that.

Preoperative and postoperative analysis of site-specific pelvic support defects in 81 women treated with sacrospinous ligament suspension and pelvic reconstruction

Bobby L. Shull, MD,[a] Charles V. Capen, MD,[a] Mark W. Riggs, PhD,[b] and Thomas J. Kuehl, PhD[a]

Temple, Texas

OBJECTIVES: The objectives of this study were to identify factors that predict long-term success, defined as the absence of anatomic defects, in women undergoing pelvic reconstruction and to identify which defects most frequently persist or recur.

STUDY DESIGN: Eighty-one women treated by sacrospinous ligament suspension and pelvic reconstruction between 1984 and 1990 had site-specific analysis performed preoperatively and at consecutive postoperative visits. The findings at the 6-week postoperative visit and subsequent visits were compared for each of five sites: urethra, bladder, cuff, cul-de-sac, and rectum.

RESULTS: The Fisher exact test showed that patients with no support defects at the 6-week visit were less likely to require subsequent repair than patients who had any defect at that visit ($p = 0.003$). Thirteen patients with subsequent or persistent cystoceles had no bladder repair performed at the time of the study procedure. However, even with repair the bladder was the most likely site for persistence or recurrence.

CONCLUSION: Absence of any pelvic support defect at the 6-week postoperative visit is associated with a 3% likelihood that the patient will require subsequent reconstructive surgery within 2 to 5 years. The anterior segment provides the greatest challenge to restoration of normal anatomy. (AM J OBSTET GYNECOL 1992;166:1764-71.)

Key words: Pelvic support defects, sacrospinous ligament suspension, anatomic assessment, pelvic support index

Every honest surgeon of extensive and long experience will have to admit that he is not entirely and absolutely satisfied with his long term results of all his operations for prolapse and allied conditions.

Richard TeLinde[1]

Nichols[2] and Morley and DeLancey[3] have reported excellent success with sacrospinous ligament suspension of the prolapsed vaginal cuff. Morley and DeLancey observed that 22% of their patients monitored >1 year had "mild to moderate cystoceles" or "symptomatic cystoceles." Nichols has not specifically commented on failures other than "recurrent eversion."

Baden et al.[4] previously reported a pelvic profile based on analysis of six individual sites in the pelvis: urethra, bladder, cervix or cuff, cul-de-sac, rectum, and perineum. All sites are scored with the patient recumbent and straining down, allowing the surgeon to grade sites under stress. We have used a modification of their vaginal profile to assess five sites—urethra, bladder, cervix or cuff, cul-de-sac, and rectum—to analyze our patients with pelvic support defects. Nagata and Kato[5] used a similar scoring system to evaluate nine patients who had sacrospinous ligament suspension procedures.

The purpose of this project was to describe site-specific pelvic support defects in patients who have had sacrospinous ligament suspension of the vaginal cuff and pelvic reconstruction. Preoperative and postoperative assessments of each vaginal site were compared to evaluate factors that affect immediate success or failure. Patients were monitored, in some cases for >5 years after surgery, to compare their immediate postoperative examination with subsequent assessments to identify factors that predict long-term success as defined by the continued absence of defects at any site and to predict the need for subsequent surgery to repair defects at any site.

Material and methods

Between November 1, 1984, and October 31, 1990, 81 women underwent sacrospinous ligament suspen-

sion and vaginal reconstruction for a variety of pelvic support defects. Before surgery each patient was objectively evaluated to assess the severity of support loss at five sites in the vagina: urethra, bladder, cervix or cuff, cul-de-sac, and rectum. All were examined in the dorsal lithotomy position, straining, and with the examining physician using a split speculum to visualize each site. Each site was scored on a scale of 0 to 4, with 0.0 indicating normal support. The cervix or vaginal cuff with 0.0 score is supported at or above the level of the ischial spines. The other sites have 0.0 score when they do not descend past the midvaginal axis, a plane extending from midhymen posteriorly to the apex, with straining. The scores of 1, 2, 3, or 4 are assessed when the site descends past the midvaginal axis halfway to the hymen (1), to the hymen (2), halfway out of the hymen (3), or fully outside the hymen (4). A pelvic support index is defined as the average score for all five sites in each patient. A patient with no defects has a pelvic support index of 0.0, and a patient with maximum loss of support at all five sites has a pelvic support index of 4.0. We tested the relationship between the 6-week postoperative pelvic support index and long-term success or lack of success in achieving anatomic restoration. If such a relationship exists, it can be used to identify the group of patients who are at an increased risk for further reconstructive surgery.

Results

Eighty-one women between 33 and 84 years of age (64 ± 11 years, mean ± SD) with pelvic support defects underwent sacrospinous ligament suspension and pelvic reconstruction. Previous pelvic surgery was documented in 72% of the patients (Table I). Preoperatively, all patients had at least one site protruding to or through the hymen. Fifty percent had ≥1 sites protruding halfway outside the hymen, and 38% had ≥1 sites protruding entirely outside the hymen. The percentage of patients with support loss at specific sites is shown in Table II. All patients required not only sacrospinous ligament suspension but a variety of other reconstructive procedures (Table III).

At the time of the first postoperative visit, 66 (81%) patients had no anatomic defects at any of the five vaginal sites (pelvic support index = 0.0), 14 (17%) patients had one or two sites protruding halfway to the hymen (pelvic support index > 0.0), and one (2%) had a defect to the hymen; however, none of the defects were larger than they had been preoperatively (Fig. 1). Eight of the 15 patients without normal support (pelvic support index > 0.0) had postoperative defects in bladder support, yet none had either a cystocele repair or retropubic urethropexy performed at the time of sacrospinous ligament suspension. Four of the 15 had cystocele repair and 3 had rectocele repair; however, in each case a defect persisted halfway to the hymen. Four of the 15 patients required further reconstructive surgery within 3 years of the original repair. One additional patient had a cystocele protruding halfway outside the hymen but she was too fragile for further surgery.

Thirteen patients with normal support (pelvic support index = 0.0) at the first postoperative visit later had anatomic defects at ≥1 sites. Five of the 13 patients who developed defects in bladder support had had no cystocele repair at the original surgery. Seven had had cystocele repair but subsequently had recurrent cystoceles. In only one case did the bladder protrude halfway outside the hymen, and that patient has had no progression in the size of the defect in 4½ years. One of these 13 patients has an enterocele to the hymen. None have had further surgery.

Forty-one of the 81 patients have had periodic pelvic exams for >2 postoperative years. Thirty of the 41 had

no defects at the first postoperative visit (pelvic support index = 0.0). Nine of those 30 subsequently developed defects at one or more sites over the next 2 to 5 years. Only one has a site extending outside the hymen.

The remaining 11 patients with any support defects (pelvic support index > 0.0) at the first postoperative visit have been monitored >2 years. Four of these 11 have had further surgery, and 1 other has tissue outside the hymen. Three had cystoceles, 1 a rectocele, and 1 a recurrence of her cuff prolapse.

The Fisher exact test showed that patients who have normal support (pelvic support index = 0.0) at the first postoperative visit are less likely to have tissue outside the hymen or to require surgery in the next 2 to 5 years than patients who have any support defect (pelvic support index > 0.0) at the first postoperative visit ($p = 0.003$) (Table IV).

Twenty-eight of the original patients demonstrated ≥1 defects at ≤5 years of surgery (Tables V and VI). Thirteen of the 28 have bladder support defects that were not repaired at the original procedure. Ten have had defects protruding to or through the hymen; four of those patients have had further surgery. The remaining 18 have no defects protruding to the hymen and are asymptomatic. All 18 have pelvic support indexes lower than their preoperative pelvic support indexes; however, they do not have full anatomic restoration. The principal site of support loss during the follow-up period was the bladder.

Comment

Pelvic reconstruction for vaginal prolapse is among the most challenging operative procedures in benign surgery. The surgeon must attempt to accomplish three separate but interrelated goals: restore anatomy (correct the anatomic defects), maintain or restore normal bowel and bladder function, and maintain vaginal capacity for sexual intercourse. Most authors report on their success in preventing cuff prolapse but do not objectively describe all the preoperative or postoperative anatomic defects. Consequently, analysis of factors that predict success or failure of anatomic restoration is impossible. Preoperative and postoperative analysis of visceral and sexual function is also important. We chose not to address these two parameters in our current report.

We have described a method of preoperative and postoperative assessment of five anatomic sites in the vaginal canal: urethra, bladder, cervix or cuff, cul-de-sac, and rectum. On the basis of our data, the patient

‡Three patients with support defects outside hymen underwent repeat surgery.

returning for her first postoperative visit with no defects (pelvic support index = 0.0) has a 3% chance of having any defect to or through the hymen in ≤5 years. When she has any defect (pelvic support index > 0.0) at the first visit, she has a 45% chance of having a defect protrude outside the hymen in ≤5 years. These defects may require more surgery to relieve symptoms.

In our series 13 (16%) patients who first returned with defects or later had defects had poor preoperative support for the bladder (halfway to the hymen) but had no bladder repair performed during the original surgery. The surgeon either underestimated the severity of the defect on preoperative examination or believed that repair of the other defects was sufficient to minimize or correct the anterior defect. Bonney[6] addressed this problem when he discussed the potential effects of "retroversion of the vagina" in 1934. He suggested retroversion itself probably causes few symptoms; however, it is "a step towards prolapse of the anterior vaginal wall," opening the anterior cul-de-sac and allowing "abnormal pressure" to be exerted on the anterior vaginal wall and underlying fascia.[6] We have observed that patients with sacrospinous ligament suspension have an exaggerated posterior axis of the vagina, perhaps retroversion as described by Bonney. If his theory is accurate, we have predisposed all our patients to anterior defects in much the same way a high retropubic urethropexy predisposes a woman to defects in the posterior cul-de-sac. In the patients with anterior loss of support (cystocele), no matter how slight, we should consider repairing the bladder support to minimize the effects of "vaginal retroversion." Two of the four patients who required repeat surgery might have been spared the second operation if the first had included repair of the anterior segment.

The other 15 (18%) patients had correction of all defects that subsequently persisted or recurred. We can only speculate whether surgical technique, suture material, wound healing, tissue strength, or alteration in the vaginal axis played major roles in these patients. None have had further surgery. None have complaints with prolapse.

Table VI. Percentage of 28 patients with loss of pelvic support at each site and by each score during postsurgical follow-up period

	Vaginal support scores				
Vaginal site	*0*	*1*	*2*	*3*	*4*
Urethra	64	32	4	0	0
Bladder	7	57	18	18	0
Cuff	96	0	0	4	0
Cul-de-sac	92	0	4	4	0
Rectum	92	4	0	4	0

The prolapsed vaginal cuff was managed successfully in 98% of patients. Unfortunately, defects in bladder support were not managed as successfully. More accurate preoperative assessment of the anterior segment (bladder and urethra) should reduce the likelihood of missing a defect either in the office or in the operating room. We are currently evaluating the proper surgical technique to repair defective support for the bladder and urethra. Transvaginal reattachment of the periurethral and perivesical fascia to the tendinous arch appears to be the correct anatomic approach to consider.

Our data show that successful surgical management of the patient with anatomic support defects requires accurate preoperative and intraoperative identification of each defect and a specific reconstructive procedure to correct each defect. Sacrospinous ligament suspension is an important part of total pelvic reconstruction.

Oncologists stage tumors to compare results of different treatment modalities and to offer prognosis for cure or recurrence. Infertility surgeons stage endometriosis to compare results of therapy and offer prognosis for success. Unfortunately, pelvic reconstructive surgeons have not used an objective classification for

pelvic support defects. As a result, most reports on pelvic reconstruction compare apples to oranges, offering the serious reconstructive surgeon little objective information with which to plan an operation or to counsel a patient regarding prognosis. We hope that an objective, site-by-site, anatomic analysis of preoperative and postoperative physical findings will stimulate others to call for an approach to the staging of pelvic relaxation anatomic defects, allowing surgeons everywhere to communicate accurately with one another.

The authors thank Janice E. Hudgins for assistance with manuscript preparation, and Vickie Behrens for coordinating patient follow-up.

Discussion

Dr. Sam P. Patterson, Memphis, Tennessee. I thank Dr. Shull and his coauthors for sending me their manuscript on sacrospinous ligament fixation and its revision in advance of this meeting. I also thank Dr. Podratz for asking me to discuss this paper and for allowing me to assume this podium for the first time since I had the honor of delivering the Presidential Address to this association in this room in 1983. I offered to defer to any younger volunteer; there apparently being none, here I am. Perhaps this could be because of the Cruikshank-Morley sparring episode of 1989.

I agree with the authors that pelvic reconstruction for prolapse is a challenging gynecologic procedure both historically and contemporaneously, as is evidenced by the multitude of techniques advocated throughout the years. As the ages of my referring physicians and my patients advance with my own, I see increasing numbers of women with recurrent severe degrees of prolapse and associated genital relaxations. Because of Drs. Morley and Cruikshank's enthusiastic advocacy of sacrospinous fixation for the prolapsed vaginal vault and discussions with David Nichols, I have performed or assisted with nine such procedures in the past year since our meeting in Louisville. Most authors attest to few complications, but there was a recent report of massive postoperative vaginal evisceration.[1] Thus far the incidence of recurrent vault prolapse after sacrospinous fixation seems small; but as years pass undoubtedly we shall see increasing numbers as the authors quote Dr. TeLinde's experience.[2] Others have had less than perfect results with vaginal repairs, or we would not have had modifications we associate with Heaney, McCall, Halban, Moschowitz, Kelly, Raz, Marshall, Machetti, Burch, Pereyra, Stamey, and Krantz. President Youngblood likewise has discussed disappointing results with surgical correction of stress urinary incontinence and has advocated Richardson's paravaginal defect repair.[3]

The authors' efforts to identify factors that predict long-term success are admirable and should be assessed for all surgical procedures. Numeric grading with scores of 1 to 4 for five sites is suggested, and a pelvic support index is defined as an average of these. Many numbers are reported in the tables, but the text refers only to a pelvic support index of 0 or >0. I ask Dr. Shull if a simple report of recurrence of cystocele, rectocele, enterocele, or prolapse might have made the results more understandable. The authors report that a patient with a pelvic support index of >0 on the first postoperative visit has a 45% chance of a defect protruding outside the hymen within five years. If accurate, this figure only includes those patients operated on during the first year of the study. If this figure includes patients operated on from 1987 on, 5 years have not lapsed, and that postoperative defect incidence would be higher.

I congratulate Dr. Shull et al. on their reported successful support of the vaginal cuff. In the comment the authors state that patients with a pelvic support index of 0 on the first postoperative visit have a 3% chance of having a defect to or through the hymen in ≤5 years. The data report one cystocele through the hymen and one enterocele to the hymen. These figures do not seem compatible. There were 41 patients monitored for >2 years; therefore 40 patients were monitored for <2 years. Restoration of visceral and sexual function is stated as a surgical goal, but these important physiologic functions are not addressed. Perhaps this should be considered a preliminary report, and subsequently we can be presented with larger numbers of women monitored for a longer time with appraisal of physiologic sexual and excretory function. I agree with their recommendation of an objective site-by-site preoperative and postoperative analysis of findings, but find their numeric averaging confusing, especially the repeated jumping from numbers to percentages in the text. Postoperative emphasis seems to be on specific site defects and not on pelvic support index, the original thrust of the paper. Objective descriptions of specific preoperative defects and reporting of postoperative results, both successes and failures, and recurrences would be more informative, particularly if addressed both anatomically and functionally.

Thanks to the authors for allowing me to participate in this discussion of fundamental gynecologic surgery.

DR. LESTER A. BALLARD, JR., Cleveland, Ohio. Drs. Baden, Walker, and Shull from the Scott & White Clinic have had long and recognized interest in the classification of pelvic relaxation. Dr. Baden[1] made a significant attempt at classification in 1968, grading six vaginal areas: urethra, bladder, prolapse, cervix or vaginal cuff, cul-de-sac, rectum, and perineum. The strain at each site was graded from 0 to 4, depending on the degree of relaxation: 1 is halfway to the hymen, 2 is to the hymen, 3 is halfway past the hymen, and 4 is fully past the hymen. This classification allows individual preoperative and postoperative profiles to be compared.

Drs. Nagata and Kato[2] modified Dr. Baden's classification by deleting the perineum, leaving five areas and creating the urethrocele, cystocele, vaginal vault prolapse, enterocele, rectocele (UCPER) operative score. Each area is again graded from 0 to 4, and scores can still be compared before and after surgery.

Dr. Shull et al. use these same five areas and scores, but they average them to make the pelvic support index. They have applied this index in 81 cases to illustrate its use.

It is important that we adopt a common anatomic classification to prevent the many misunderstandings that have resulted from each author's perception of the classification. In 1989 at Central Association, I discussed Dr. Cruikshank's paper on sacrospinous fixation. I tried to point out the differences between his classification and that of Drs. Morley and DeLancey. There can be, and is, a certain distrust of another person's staging.

The ideal classification would include anatomic measures and symptoms to indicate the need for and type of surgery. However, Dr. Shull has based his index solely on anatomic defects, although there are patients without anatomic defects who have symptoms and patients with anatomic defects who have no symptoms. Although I agree that anatomic assessment must be done with straining in the lithotomy position, I am also impressed with how much more relaxation can be appreciated when the patient is examined while standing. Some urogynecologists grade the cystourethroceles by having the patient stand with a full bladder for a rest and stress voiding cystourethrogram to show maximum anterior relaxation.

In Dr. Shull's analysis of 81 sacrospinous ligament suspensions, 26 (32%) patients had the procedure done with a hysterectomy and 58 (68%) had the procedure after hysterectomy for vaginal cuff prolapse. In Table II, after converting the percentages to numbers of patients, I find 371 preoperative defects of various grades. Of a possible 405 defects, only 34 sites showed no defects. All 81 cases had defects of the cervix or cuff with grades 1 to 4 in addition to 67 urethra, 76 bladder, 68 cul-de-sac, and 78 rectal defects. Preoperatively, the anterior wall represented 38% of the total defects. In Table III 64 (79%) patients had cystocele repair or retropubic urethropexy, leaving 17 patients without anterior wall repair. There were 3 transient postoperative nerve injuries on the right side ascribed to "too high leg holders," not to surgical trauma. On which side were these 3 sacrospinous ligament suspensions done?

At the time of the first postoperative visit, 66 (81%) patients had pelvic support indexes of 0, but 15 (19%) patients had pelvic support indexes >0. Fourteen patients had grade 1 defects at ≥1 sites, but "none of these defects were larger than they were preoperatively." What were the grades preoperatively? Of these 15 patients with postoperative pelvic support indexes >0, eight had bladder defects that had no anterior wall repair. What were the preoperative grades of these eight patients? The other seven patients had surgical repair: four cystocele and three rectocele. Four of 15 defects required further reconstructive surgery, but from what preoperative group did they come? Thirteen patients who had pelvic support indexes of 0 at 6 postoperative weeks later had ≥1 defects. Five of these patients had no previous anterior repair but were scored 0 at 6 weeks, presumably with no defect present. In 7 patients who had cystocele repair, cystocele recurred: 6 grade 1 and 2, 1 grade 3, and 1 grade 2 enterocele. When comparing 41 of 81 patients monitored for >2 years, there were 30 whose pelvic support index was 0 at first postoperative check. Nine had defects, with 8 grade 1 or 2 and 1 grade 3. The 11 patients with pelvic support indexes >0 had 1 cuff prolapse, 3 cystoceles and 1 rectocele, with 4 subsequently requiring surgery. Therefore 1 (3%) of 30 pelvic support index = 0 had a grade 3 defect, and 5 of 11 pelvic support indexes > 0 (45%) had grade 3 defects.

Dr. Shull combined all of the 28 (34%) postoperative defect cases without regard to pelvic support index or length of follow-up. Thirteen patients had no initial bladder repair, which has been previously noted: five from the pelvic support index = 0 group and eight from the pelvic support index > 0 group. Ten of these patients had grade 2 and 3 defects, and 4 of these had surgery. The remaining 18 patients with grade 1 defects were asymptomatic.

Table VI shows 41 postoperative defects. Of these, 10 were of the urethra and 26 were of the bladder; that is, 36 (87%) of 41 were anterior defects. This compares with 38% for preoperative anterior defects. The other postoperative defects show 1 grade 3 vault, two grade 2 and 3 cul-de-sacs, and 2 grade 1 and 2 rectal defects.

Dr. Shull has shown that whether anterior defects are repaired or not, the anterior wall is the area in which defects develop. Dr. Nichols[3] recently stated in regard to sacrospinous ligament suspension that "full-length

anterior colporrhaphy with special attention to support of the cystourethral junction is performed almost without exception." I agree that the anterior wall is the major defect with sacrospinous ligament suspension. In our evaluation of 110 sacrospinous ligament suspension patients at Cleveland Clinic from 1978 through 1985, it was apparent that the anterior wall was a problem. Although we had 3 vault recurrences, we had 5 grade 2 cystoceles, 3 with stress urinary incontinence and 8 with transitory stress incontinence. I thought at this time that I needed to do better anterior repair with either pubourethral suspension or with the retropubic or retrovaginal needle procedure. However, when I reviewed our next 158 sacrospinous ligament suspension patients from 1986 through 1989, it was apparent that we had not improved the anterior wall defects and stress incontinence in spite of a diligent preoperative attempt to sort out anatomic and sphincter incontinence and bladder instability. On evaluation of these 158 sacrospinous ligament suspension patients we had 3 grade 3 vault prolapses but had 2 grade 2 anterior enteroceles, 10 grade 2 cystoceles, 1 grade 3 cystocele and 6 with stress incontinence. I became suspicious that the sacrospinous ligament suspension operation was contributing to the anterior wall defects.

Dr. A. Cullen Richardson et al.[4] has pointed out that when we pull the vault either too far anteriorly or too far posteriorly we produce a compensatory abnormality. It will be interesting to know if a paravaginal repair of the anterior wall in patients with sacrospinous ligament suspension, which Dr. Shull presented to the Central Association in 1988, will decrease these defects. Will doing a perirectal vault suspension along with paravaginal suspension improve the anterior wall? In 237 of the 310 sacrospinous ligament suspension I have done, my enthusiasm for the procedure has been tempered because of the defects of the anterior wall.

I applaud Dr. Shull's efforts to create the pelvic support index, but I do not think it is as helpful as the preoperative and postoperative profiles of each defect. The index reduces specificity because it replaces five numbers with one, and it does not provide any corresponding increase in use. It seems to me that clinical decisions still have to be made on the basis of a profile and not on the index. I guess I am a splitter rather than a lumper. However, I believe that Dr. Shull and his group have stimulated us all by calling for, as he says in the last sentence of his manuscript, "an approach to the staging of pelvic relaxation anatomic defects, allowing surgeons everywhere to communicate accurately with one another."

Dr. Mickey Karram, Cincinnati, Ohio. I would like to ask Dr. Shull how he evaluated women who were initially seen with primary complaints of lower urinary tract dysfunction, whether it be voiding dysfunction or urinary incontinence. Did these patients undergo urodynamic evaluation?

In your series there was a small group of patients who underwent retropubic procedures in conjunction with vault suspension. However, most of the patients just underwent standard anterior repair. How did you decide which operation to do?

Last, what is the best way to test preoperatively for potential stress incontinence in patients with massive pelvic relaxation?

Dr. G. Rodney Meeks, Jackson, Mississippi. I rarely see a patient without an anterior defect who needs a cuff suspension. I wonder why one third of your patients fell into this catagory.

Second, can you overcorrect the vaginal defect by pulling the vagina too far back toward the ligament? Is there a depth that you try to achieve when you put the suture in, or do you try to pull the vaginal cuff as far back as possible?

Dr. Jeffery Cornella, Scottsdale, Arizona. It is also our impression that sacrospinous fixation increases the incidence of subsequent anterior wall defect, and we support the concept of prophylaxis. However, in the last number of years I have noted increased case reports documenting bowel eviscerations through the vagina related to concomitant needle suspension and sacrospinous suspension, even though previously in the world literature there have been <39 reports associated with gynecologic surgery.

Would Dr. Shull address whether this combination of procedures weakens the apex, how he tempers his prophylaxis regarding the apex of the vault, and how he approaches patients who have decreased thickness of the apical tissues?

What number and type of sutures does Dr. Shull use, and how many bites are taken into the vagina and ligament?

Dr. Stephen H. Cruikshank, Minneapolis, Minnesota. Why does Dr. Shull not examine these patients in the standing position; this does test the anatomic support to the *n*th degree because that is how humans usually are, in the standing position.

At the time of hysterectomy do you evaluate these people, and have you done it preoperatively both in the supine and the erect position so that you can do the right procedure?

Third, I think that we should understand the definition of prophylaxis before you answer that, and that means to prevent or to ward off. I looked that up in Webster's dictionary before I came this year.

Dr. Shull (Closing). Dr. Patterson said it would be simpler if there were not so many numbers. He is exactly right. I fretted over my manuscript and asked

other people to help with that concern; however, there was no way for us to know what the outcome would be without collecting the information. To begin with fewer observations would have been to reinvent a less specific description just as Dr. Clayton Beacham reported, that Dr. Cruikshank had in his paper, and that Dr. Morley used in his. We did not choose to start with something simple because we wanted to understand more about the problems of support defects and their repair. To relay that information to you it is important to give numbers. We tried to make our conclusions more concise by referring to patients who had abnormal support or normal support. If you believe it is important to communicate about pelvic support defects in a manner similar to staging, you know that the descriptions must be detailed, reproducible, and accurate in the same way that definite findings are required to stage genital cancers. I agree with both commenters that the pelvic support index may be confusing; however, collection and analysis of the information appear to be important.

Dr. Ballard suggested that we not only should have anatomic information but also symptomatic information. The purpose of our study, however, was to look at anatomy, not visceral function and not sexual function.

Dr. Nichols, who has written extensively about his surgical experience with sacrospinous ligament suspension, has not given detailed comments regarding follow-up of other areas of the vaginal canal. I do not know or presume to say what type of success he has with areas other than the cuff.

Dr. Ballard also asked about some of the information in the tables. I will look that up privately.

Dr. Mickey Karram asked about lower urinary tract dysfunction, why we chose to do a retropubic or a paravaginal repair, and what the test of choice is. The test of choice for me is a provoked full-bladder stress test when the apex of the vagina is replaced. We filled the bladder to the point of maximum sensation, reduced the apex with a sponge stick or a cotton swab, and had the patient cough and strain while sitting in a birthing chair. If the patient leaks urine under those circumstances, we choose vaginal or retropubic paravaginal defect repair in association with the other reconstructive procedures.

Dr. Meeks asked why we did not do an anterior repair. First, in some patients we did not make the right diagnosis. I am sure we missed the defects. Second, in some of the people we identified the defects preoperatively, but when we replaced the apex to the ischial spine (performed in the office) and had the patient bear down maximally, it was our impression the anterior segment did not descend. We were wrong.

Do we go to the spine? We try to take the apex of the vagina to the sacrospinous ligament. If that is not possible we use levator fascia just anterior to the spine, a procedure Dr. Meeks is very familiar with. The procedure was reported in *Southern Medical Journal* in 1963 by Byron Inman. The group at Mississippi has used that repair extensively. I have another group of patients I did not report today in whom I have used levator fascia as a point of attachment.

Jeff Cornella has asked about suture material. We have used permanent sutures in the right ligament, Novafil or Ethibond. There was not enough information for me to report whether it made a difference as to which we used. Steve Cruikshank asked if we examined patients when they were standing. Yes and no. I do examine some standing patients. I find it quite difficult to look at each site with the patient in the standing position. I can not fathom being able to do that accurately. I could tell if something were coming out, but it would be quite difficult to evaluate urethra, bladder, cuff, cul-de-sac, and rectum individually with the patient in the standing position.

Cervical cytology: A randomized comparison of four sampling methods

Marian L. McCord, MD,[a] Thomas G. Stovall, MD,[a] Janel L. Meric, MD,[a] Robert L. Summitt, Jr., MD,[c] and Sidney A. Coleman, MD[b]

Memphis, Tennessee

OBJECTIVE: The purpose of this study was to compare smear quality and endocervical cell recovery of four cervical smear sampling devices.

STUDY DESIGN: Two thousand fifteen patients undergoing routine cervical smears at the University of Tennessee Obstetrics and Gynecology clinics were randomly assigned to a cotton swab-spatula, Cytobrush-spatula, Cervex-Brush or Bayne Pap Brush. The cytopathology laboratory, blind to method, used specific criteria to grade smears as being optimal, adequate, marginal, or inadequate. Statistical analysis was by the χ^2 and analysis of variance tests.

RESULTS: No statistical differences occurred among the groups for nonpregnant patients. For pregnant patients smear quality was improved with both Cytobrush-spatula and Bayne Pap Brush versus cotton swab-spatula ($p = 0.0301$ and 0.0004, respectively); cotton swab-spatula had fewer endocervical cells than the Cytobrush-spatula ($p = 0.0001$), Cervex-Brush ($p = 0.0286$), and Bayne Pap Brush ($p = 0.0081$).

CONCLUSIONS: The cotton swab-spatula and Cytobrush-spatula appear to be the most effective screening methods for nonpregnant and pregnant patients, respectively. (Am J Obstet Gynecol 1992;166:1772-9.)

Key words: Papanicolaou smear, cervical smear, Cytobrush, Cervex-Brush, Bayne Pap Brush

Routine cytologic screening for cervical dysplasia has effectively decreased the incidence of cervical carcinoma and its associated mortality[1]; however, the false-negative rate for Papanicolaou smears is estimated to be as high as 40%.[2] Suboptimal smear quality is a known potential source for such error. Because the squamocolumnar junction is at greatest risk of having neoplasia develop, adequate cell sampling of this area is necessary to assure the high sensitivity of the Papanicolaou smear. The presence of columnar endocervical cells on the smear is accepted as evidence that the squamocolumnar junction has been sampled. Large studies have shown that the presence of endocervical cells is associated with an increase in the proportion of smears showing cellular atypia and dysplasia, therefore resulting in higher sensitivity.[3-6]

To improve Papanicolaou smear quality and reliability, numerous cell collection devices and techniques have been introduced since the original method described by Papanicolaou in the 1940s.[7-11] The ideal instrument would provide adequate ectocervical and endocervical cellular material without undue mucosal damage to the cervix and without inducing bleeding that could obscure cytologic evaluation. The technique should be relatively simple and produce similar quality Papanicolaou smears regardless of the experience of the medical personnel collecting the samples. Therefore the purpose of this study was to compare four commercially available Papanicolaou smear–collecting devices to determine which method produces the highest quality smear in pregnant and nonpregnant patients.

Material and methods

The study group included all patients undergoing Papanicolaou smear evaluation between October 1990 and February 1991. Subjects were evaluated in the outpatient clinics of the Regional Medical Center in Memphis, the teaching hospital associated with the University of Tennessee, Memphis. Papanicolaou smears were performed by faculty, residents, and medical students, all of whom had been instructed in the proper technique of specimen collection with each device. Only patients who had previously undergone hysterectomy or who had previously been treated for cervical carcinoma were excluded. Patients were not excluded because of their gestational status.

Demographic data obtained at the time of the cervical

smear included age, gravidity, parity, gestational status, date of last menses, current use of oral contraceptive, history of previous abnormal Papanicolaou smear, and previous cervical cryotherapy, cervical conization, or cervical laser treatment. Gestational status was defined as (1) pregnant, any gestational age; (2) postpartum, <8 weeks from delivery of pregnancy >20 weeks' gestational age; and (3) nonpregnant. The training level of the person taking the smear was also recorded.

Patients were randomly assigned by computer-generated numbers to one of four methods of Papanicolaou smear collection. The four cytologic sampling methods evaluated were (1) cotton swab and modified Ayre spatula, (2) Cytobrush (Medscand (U.S.A.), Hollywood, Fla.) and modified Ayre spatula, (3) Cervex-Brush (Unimar, Inc., Wilton, Conn.), or (4) Bayne Pap Brush (Medical Dynamics Inc., Englewood, Colo.) (Fig. 1). The Papanicolaou smear collection method was per the manufacturer's recommended instructions. Each method was preceded by use of the modified Ayre spatula, which was rotated circumferentially over the ectocervix; the end appropriate for the patient's gestational status was used. The cotton swab and Cytobrush were each gently inserted into the endocervical canal and rotated 360 degrees. The central bristles of the Cervex-Brush were gently inserted into the endocervix until the lateral bristles bent fully against the ectocervix. The Cervex-Brush was rotated three to five times to the right and left. The sample as applied to the slide with a paint stroke of each side of the bristles. The Bayne Pap Brush is malleable and can be adjusted to conform to the shape of the cervix. The endocervical portion of the brush was gently inserted into the endocervical canal until there was continuous application of the brush from the endocervix to the ectocervix. The brush was rotated 360 degrees. All smears were placed on a single glass slide and immediately fixed with 95% alcohol.

All smears were evaluated by the Cytopathology Laboratory associated with the Department of Pathology, University of Tennessee, Memphis. The laboratory is accredited by The College of American Pathologists. The cytopathology technicians and cytopathologist were blind as to the sampling method. Initially one of four cytopathology technicians interpreted the slides. The cytopathologist reviewed any sample about which the cytotechnician was uncertain, 200 randomly selected samples, and all samples that were deemed unsatisfactory or abnormal. Recovery of endocervical cells and quality of the smear were documented. The presence of inflammation, bacteria, *Monilia, Trichomonas* excessive red blood cells, and drying effect were noted.

Smear quality was designated as inadequate, marginal, adequate, or optimal. A smear was considered inadequate if (1) it lacked an endocervical component, (2) excess blood or inflammation obscured the epithelial cells, (3) the smear dried before fixation. (4) the ectocervical component was insufficient, or (5) the smear was too thick. A smear were graded as marginal if the quality was compromised, but not obscured, by blood, inflammation, or air-drying; in addition, ectocervical cells were present, and the smear contained ≥25 endocervical cells. The quality of adequate and optimal smears was uncompromised by the above-noted factors. Ectocervical cells were present. Adequate smears contained ≥25 but <50 endocervical cells. Optimal smears contained ≥50 endocervical cells. If the smear were deemed inadequate or marginal, the reason was recorded. Statistical analysis was performed by the Department of Biostatistics. Analysis of variance and χ^2 tests were used.

Results

A total of 2015 patients were randomized to be tested with one of four cervical cytologic sampling devices: 503 (25.0%) cotton swab and modified Ayre spatula, 501 (24.9%) Cytobrush and modified Ayre spatula, 505 (25.0%) Cervex-Brush, and 506 (25.1%) Bayne Pap Brush. Table I summarizes the demographic data of the patients included in the clinical trial. There was no statistical difference among the four sampling groups regarding age, gravidity, parity, gestational status, oral contraceptive use, postmenopausal satus, and training level of the examiner. The number of patients in each group with histories of previous abnormal Papanicolaou smears or cervical surgery, including cryotherapy, laser ablation, or conization, was not statistically different.

There was a significant difference in Papanicolaou smear quality between pregnant and nonpregnant patients (postpartum patients were too few for statistical evaluation). Five hundred two (85.4%) of 588 nonpregnant patients had optimal-adequate smears, compared with 1004 (74%) of the 1356 pregnant patients ($p < 0.001$). Inadequate smears occurred in 67 (11.4%) of the 588 nonpregnant patients and 242 (17.8%) of the 1356 pregnant patients ($p = 0.0050$). Endocervical cells were absent in 164 (12.1%) of the 1356 pregnant patients, compared with 48 (8.2%) of the 588 nonpregnant patients ($p = 0.0220$). Excessive inflammation was found on cervical smears of 212 (15.6%) of the 1356 pregnant patients and 72 (12.2%) of the 1588 nonpregnant patients ($p < 0.0001$). There was no statistical difference between groups for excessive blood.

Cervical smear quality for each sampling device was assessed separately for nonpregnant-postpartum and pregnant patients. Because both optimal and adequate smear grades are acceptable to the practitioner, these were combined into one category for statistical comparison. For nonpregnant and postpartum patients

there was no statistical difference in smear quality among the four sampling groups (Table II).

The smear quality results of the 1356 pregnant patients sampled are listed in Table III. Optimal and adequate Papanicolaou smears were increased for the Cytobrush-spatula and the Bayne Pap Brush versus the cotton swab–spatula ($p = 0.0301$ and 0.0004, respectively). Fewer inadequate smears occurred with the Cytobrush-spatula versus the cotton swab–spatula ($p = 0.0317$), the Bayne Pap Brush versus the cotton swab–spatula ($p < 0.0001$), and the Bayne Pap Brush versus the Cervex-Brush ($p = 0.0077$). There were no other statistical differences occurring among sampling devices.

Factors accounting for marginal and inadequate smears for all patients are summarized in Table IV. Absent endocervical cells was the single most common reason for the Papanicolaou smears to be judged inadequate. In the pregnant patient the cotton swab–spatula was less likely to recover endocervical cells than the Cytobrush-spatula ($p = 0.0010$), the Cervex-Brush ($p = 0.0137$), and the Bayne Pap Brush ($p = 0.0026$). There was no differences among the other three sampling devices. This trend was evident, but not statistically significant, for the nonpregnant patient. For all patients excessive blood was more common in the Cytobrush–Ayre spatula smear as compared with the cotton swab–Ayre spatula ($p = ?$) and the Cervex-Brush ($p = ?$). No statistical difference occurred between the sampling methods for excessive drying or excessive inflammation. Smears that were too thick or too thin occurred too infrequently to be statistically meaningful.

Detection of cervical dysplasia was constant for all Papanicolaou smear sampling groups. Dysplasia was present in 31 (6.2%) cotton swab–spatula smears, 29 (5.8%) Cytobrush-spatula smears, 31 (6.1%) Cervex-Brush smears, and 27 (5.3%) Bayne Pap Brush smears.

Thirty-six patients underwent colposcopic examinations and biopsies at the time their Papanicolaou smears were obtained. Eight (22.2%) patients had clumping of cervical cells on their smears; the outer third to half of the epithelial layer of their biopsy spec-

imens had been denuded. As a result, evaluation of cervical intraepithelial neoplasia grade for either the smear or the biopsy was impossible. One (12.5%) was obtained by the cotton swab–spatula, 2 (25.0%) by the Cytobrush-spatula, 4 (50.0%) by the Cervex-Brush, and 1 (12.5%) by the Bayne Pap Brush.

Comment

We believe this is the first report comparing the four commonly used sampling methods in a randomized trial in the same population, and thus the major strength of this study. Taylor et al.[7] reported a decline of suboptimal smears caused by a lack of endocervical cells from 12% to 1.7% when the Cytobrush was used in place of the cotton swab. Murata et al.[8] corroborated these findings and improved the endocervical cell yield from 61.8% to 82% by replacing the cotton swab with the Cytobrush. Concurrently they noted an increase in the proportion of Papanicolaou smears showing cervical intraepithelial neoplasia.

The Cervex-Brush was designed to sample the ectocervix and endocervix simultaneously. Vooijs[9] compared with Cervex-Brush to the modified Ayre spatula in a large series. The rate of unsatisfactory smears fell from 4.8% to 2.4%, and the presence of endocervical cells rose from 85.9% to 95.8% with use of the Cervex Brush. Laverty et al.[10] showed a statistically significant increase in endocervical cell recovery and presence of atypical squamous cells with the Cervex-Brush. However, both of these studies lacked the use of an endocervical sampling device in conjunction with the spatula in the comparison group.

In a prospective randomized trial Dotters et al.[11] reported a very low incidence of Bayne Pap Brush smears lacking endocervical cells (1.4%); 96% of these smears were optimal (containing >50 endocervical cells). Of the smears collected with the cotton swab and Ayre spatula, 19% lacked endocervical cells and only 58% were considered optimal. Dotters et al. also noted a 20% incidence of cervical bleeding when the Bayne Pap Brush was used in pregnancy and a 2.5% incidence of bleeding in nongravid patients.

This trial showed a significant improvement in smear quality for the Cytobrush over the cotton swab for pregnant patients. Frequency of inadequate smears was significantly less compared with the cotton swab–modified Ayre spatula method. Endocervical cell presence was significantly greater in the pregnant population. These differences were not statistically significant in the nonpregnant patient.

The Cervex-Brush did not demonstrate a significant change in smear quality as compared with the other groups. Endocervical cell presence was significantly improved over the cotton swab–spatula for pregnant patients. Excessive blood was seen more commonly with the Cervex-Brush than with the cotton swab–spatula.

Our study demonstrated a statistically significant improvement in smear quality for the Bayne Pap Brush as compared with both the cotton swab–spatula and the Cervex-Brush for pregnant patients. For nonpreg-

$p < 0.05$ considered significant. *NS*, Not significant.

nant patients the Bayne Pap Brush was equal to the cotton swab–spatula. Endocervical cell collection was significantly improved over the cotton swab–spatula for pregnant patients.

A concern raised but not answered in our paper is the effect of the various sampling methods on the epithelium of the cervix. As seen in eight patients undergoing colposcopies, denudation of the epithelium by the sampling techniques made histologic evaluation of the biopsy impossible. Improved cell smears may be counterproductive if cervical intraepithelial neoplasia grade and depth of involvement cannot be assessed by biopsy, thereby mandating conization. As increasingly aggressive techniques are used to sample the endocervix, this issue will demand further study.

Cost is important when mass screening is considered. The manufacturers' quoted price (as of April 1991) per unit for 1000 units is $0.07 of the cotton swab–Ayre spatula, $0.30 for the Cytobrush–Ayre spatula, $0.41 for the Cervex-Brush, and $0.53 for the Bayne Pap Brush. The cost of greater quantities may vary, but the price trend is still applicable.

On the basis of these data, the less costly method of screening is the Ayre spatula–Cytobrush combination

in the pregnant patient and the Ayre spatula–cotton swab combination in the nonpregnant patient. If only one method is to be selected, it should be the Ayre spatula–Cytobrush method.

Discussion

DR. JOHN V. KNAUS, Evanston, Illinois. In an era that has seen the Papanicolaou smear extrapolated from simple exfoliative cytology to reinvent on by the Bethesda system, Dr. McCord et al. have helped resolve several issues of daily importance to the practicing gynecologist.

First, in nonpregnant patients no significant statistical difference in Papanicolaou smear quality was noted among the four sampling methods tested. Cotton swab and spatula was judged the most cost- and smear-quality effective. In the pregnant patient the Cytobrush and spatula were most effective. Second, the detection rate of cervical intraepithelial neoplasia was equal among the four methods. As the authors state, no prior study has led to these clear results.

It is a third area, that of Papanicolaou smear adequacy as determined by the presence of endocervical cells, that requires further discussion. Of late much has been written expounding the close correlation between the presence of endocervical cells and Papanicolaou smear adequacy. Literature documenting this relationship has become an assumption of many authors. Indeed, an entire body of knowledge placing this supposition in doubt has been largely ignored. With the criteria of absent or insufficient endocervical cells, up to 30% of Papanicolaou smears may be inadequate.[1] Husain et al.[2] report this number to approach 80% in some series. In the case of a wide transformation zone, the most representative sampling may not contain endocervical cells.[3] Lee et al.[4] report endocervical cell recovery on cervical cytology smears to be independent of the clinician's length of training and experience. In a prospective study of 18,900 patients, Kivlahan found the presence of endocervial cells on Papanicolaou smears to have no statistical predictive value in detecting cervical intraepithelial neoplasia.[5]

DR. JULIAN SCHINK, Chicago, Illinois. The stated goal of Dr. McCord's study was to compare the Papanicolaou smear quality and endocervical cell recovery of four different cervical sampling systems. Her study focuses on easily measured subjective parameters, but with this study design she is unable to address the most important question: Can a given Papanicolaou smear collection system improve the sensitivity of this screening test? This study could not use Papanicolaou smear sensitivity as an endpoint for two reasons. First, the prevalence of cervical dysplasia was too low in the study population. Second, the sample size is much to small to find any difference in the dysplasia detection rate of different systems. A study of Papanicolaou smear screening would require 26,500 patients per group to demonstrate a 10% difference in detection rate at a power of 80% and $p = 0.05$. With the present study the power to detect such a difference was only 9%.

For Dr. McCord's research to be meaningful we must accept the premise that an adequate sample of endocervical cells results in a more sensitive and reliable Papanicolaou smear. In support of this premise, Rylander[1] (1977) showed that false negative Papanicolaou smears of women with invasive cancer frequently lacked endocervical cells. Furthermore, Elias et al.[2] noted severe abnormalities four times more often in smears containing endocervical cells than in smears without endocervical cells.[2] On the other hand, however, in a study of 18,914 women Kivlahan and Ingram[3] found no difference in the atypia rates between women with and without endocervical cells on serial Papanicolaou smears. Therefore the importance of endocer-

vical cells on a Papanicolaou smear remains controversial. Many prior studies have shown the same improved yield of endocervical cells with the Cytobrush, but I do not know of any large prospective study showing improved sensitivity for detection of cervical cancer of dysplasia with the use of the Cytobrush. We can safely conclude that the Cytobrush produces a cytology specimen that is more likely to contain endocervical cells; it remains to be shown whether this translates into a more sensitive test.

In this study the improvement in Papanicolaou smear quality was most noteworthy in pregnant patients. Unfortunately, the Cytobrush manufacturer cautions against the use of Cytobrush in pregnancy. My questions to Dr. McCord are (1) How do the authors reconcile this discrepancy between their results in pregnant patients and the manufacturers' recommendation? and (2) Because almost 15% of your patients have unsatisfactory smears, how do you recommend managing these patients?

The power analysis was performed by Alfred W. Rademaker, Biometry Section of Northwestern University Cancer Center. This analysis is based on a two-tailed test detecting a 10% difference ($\leq$5.53% or $\geq$6.82%) in the baseline rate of 6.2%.

Dr. John C. Morrison, Jackson, Mississippi. We in Mississippi have the same problem as Dr. McCord et al. have in Tennessee: the pregnant patient with an inadequate Papanicolaou smear that causes unnecessary patient visits. This adds greatly to the expense and to the uncertainty regarding the results.

Dr. Schink correctly points out that the manufacturer's guidelines state that the Cytobrush should not be used in pregnant patients. We have just completed a study involving 880 patients comparing Cytobrush with the cotton-tip applicator. We found that in 71% of the women the Cytobrush gave us adequate Papanicolaou smears compared with only 42% with the cotton tipped applicator, very similar to the statistics that Dr. McCord presented.

In our series of 880 patients only three had bleeding. We had a few cases, of course, with spotting. So we have no case in our series where the Cytobrush led to bleeding that was in any way dangerous; we are publishing that fact and ask the authors how many of their pregnant patients had bleeding that was heavy or caused complications.

Dr. James G. Blythe, St. Louis, Missouri. The first pictures you showed—was that a wooden or a plastic Ayre spatula? There is a statistically significant difference when collecting cells with the plastic Ayre spatula, and I certainly recommend that spatula to everybody.

We did a similar study comparing the Cytobrush with the Cervex-Brush, looking at the number of endocervical cells. We found endocervical cells to be equally as recoverable with the Cytobrush and the Cervex-Brush whether the patient was pregnant or not because the Cytobrush is not recommended for use in pregnancy. We recommend to our private physicians the use of the Cervex-Brush and the plastic Ayre spatula in pregnant patients.

Dr. Suzanne R. Trupin, Champaign, Illinois. In our practice we have been searching diligently for an affordable Papanicolaou smear, and we have switched labs a number of times over the past number of years. We find that our percentage of cervical intraepithelial neoplasia discovery is a factor of the individual pathology laboratory, as is our percentage of adequacy. Could the authors comment on this?

Dr. John Knaus, Evanston, Illinois. A recent paper in the Journal of Reproductive Medicine addressed the issue of Papanicolaou smear accuracy.[1] The training level completed and the number of years of clinical practice of the person performing the smear did not equate with greater accuracy in obtaining endocervical cells. The authors concluded that obtaining an adequate Papanicolaou smear was as much an art as a science.

Dr. McCord (Closing). I begin by addressing Dr. Knaus's questions. Whether the presence of endocervical cells will improve the detection of dysplasia is unclear. However, most studies have shown that the presence of endocervical cells on the smear is associated with improved smear quality. This, then, appears to be correlated with adequate sampling of the entire transformation zone.

Because we did not detect any significant differences in the sampling methods for the nonpregnant patient, including improved detection of dysplasia, the cotton swab is the most cost-effective method of screening for the nonpregnant patient. In the nonpregnant patient there was no significant difference in the presence of endocervical cells with any of the four methods.

Dr. Schink asked several questions. To begin, let me explain why we chose to include subjective criteria in our study. Our laboratory records the reason a Papanicolaou smear is considered inadequate. Frequently a Papanicolaou smear is unsatisfactory for reasons other than scant cellularity. Some of the reasons may be sampling-method dependent: excessive blood and air-drying effect. Other reasons, such as excessive inflammation, are not method dependent. A sampling method that collects endocervical cells yet results in poor quality smears because of cell clumping, bleeding,

or air drying should not be used. Unfortunately these criteria are subjective and vary between laboratories and individuals. The very nature of cytology and diagnosis of dysplasia is subjective.

I defer to Dr. Schink his comments on the statistical adequacy of our patient population. Our statistical data was performed by a biostatistician who assured us before the initiation of our study that our sample size was adequate.

It was noted that our conclusion for nonpregnant patients differed from other studies. Most studies evaluating sampling methods have addressed the recovery of endocervical cells as the sole criterion for recommending a method. Endocervical cell recovery is extremely variable. For instance, Murata et al. recommended use of the Cytobrush over the cotton swab as the endocervical detection rate improved from 62% to 83%. We had a detection rate of 90% for nonpregnant patients with the cotton swab. Again, this demonstrates the importance of understanding the criteria used in your laboratory.

We believe that inadequate smears, for whatever reason, should be repeated.

Both the Cytobrush and the Bayne Pap Brush have qualifiers on their packages cautioning about use in pregnancy. Before beginning our study, I spoke with representatives from both companies. Both have unpublished data documenting the safety of these devices in pregnancy. The disqualifiers remain on the packages because the data is unpublished. We did not have any known complications from any sampling methods. Patients in their third trimester of pregnancy tended to have cervical bleeding when the Papanicolaou smear was obtained with the Bayne Pap Brush. Two patients were kept in the clinical area for 1 to 2 hours for observation. Interestingly, the incidence of excess blood on smears was not increased for patients in the third trimester of pregnancy.

We used wooden spatulas with the cotton swab and Cytobrush. The use of the plastic Ayre spatula might have improved our smear quality further.

Interlaboratory variation in antiphospholipid antibody testing

Alan M. Peaceman, MD, Richard K. Silver, MD, Scott N. MacGregor, DO, and Michael L. Socol, MD

Chicago and Evanston, Illinois

OBJECTIVE: Because of the widespread use of antiphospholipid antibody testing in the evaluation of patients with recurrent pregnancy loss, we evaluated the consistency of results among laboratories testing for anticardiolipin antibody and the lupus anticoagulant.

STUDY DESIGN: A questionnaire regarding methods used and samples of blood from 20 patients were sent to five university-based and five commercial facilities for antiphospholipid antibody testing.

RESULTS: The responses of the participating laboratories to the questionnaires revealed significant differences in methods, standardization, and units of reporting. For anticardiolipin antibody, the number of specimens found to be positive for any isotype (immunoglobulin G, M, or A) varied considerably among laboratories, with a range of 5 to 13. All laboratories were in agreement (i.e., at least one isotype was present or all were absent) for only 5 of 20 specimens (25%). In contrast, lupus anticoagulant results were more reproducible, although one facility reported results markedly discordant from the other four laboratories.

CONCLUSION: These observations suggest that significant interlaboratory variation exists in antiphospholipid antibody, and particularly anticardiolipin antibody, testing and might lead to unnecessary therapeutic interventions. (Am J Obstet Gynecol 1992;166:1780-7.)

Key words: Antiphospholipid antibodies, lupus anticoagulant, anticardiolipin antibody, recurrent pregnancy loss

Antiphospholipid antibodies are circulating autoantibodies directed against negatively charged phospholipid components of cell membranes. Two particular antiphospholipid antibodies, anticardiolipin antibody and the lupus anticoagulant, have recently been implicated as possible causes of recurrent adverse obstetric outcomes. Second-trimester fetal death, early severe preeclampsia, fetal growth retardation, and maternal thrombosis have all been associated with the presence of lupus anticoagulant and anticardiolipin antibody, and these complications have been suggested as indications for antiphospholipid antibody testing. Although testing for lupus anticoagulant and anticardiolipin antibody is currently being performed by many laboratories in the United States, the College of American Pathologists does not perform proficiency testing or standardization for either assay. A method of standardized testing was proposed by the Kingston Antiphospholipid Antibody Study group at the anticardiolipin standardization workshop,[1] but these recommendations have not been accepted by all laboratories.

Therapy for prevention of poor pregnancy outcome in patients who have positive test results for antiphospholipid antibodies has been largely empiric and has included glucocorticoids,[2,3] aspirin,[2,3] heparin,[4] plasma exchange,[5] and intravenous immune globulin.[6] If significant variation exists among laboratories, it would likely result in either large numbers of patients receiving unnecessary therapies or repeat pregnancy losses in untreated patients who have false-negative results. On numerous occasions we have encountered discordant results among referral patients who have had testing in two different laboratories. These clinical observations prompted us to conduct this investigation to determine whether significant variation in either the method used or the results exists among regional and national laboratories testing for antiphospholipid antibodies.

Methods

Ten laboratories were chosen for participation in this investigation, five that were associated with university departments and five that were independent commercial laboratories. Questionnaires were sent to participants asking for (1) number of samples tested annually, (2) instructions for sample preparation and shipping, (3) description of testing used, (4) methods of standardization, and (5) units for reporting results. All laboratories approached agreed to participate with the understanding that participating centers would not be identified by name. All 10 facilities performed anticar-

diolipin antibody testing, but only five performed assays for lupus anticoagulant.

Phlebotomy was performed on 20 nonpregnant, consenting subjects who were not receiving steroids, aspirin, or anticoagulant therapy at the time. Plasma and serum were extracted in a routine manner (with and without sodium citrate, respectively, then centrifuged at 3000*g* for 30 minutes) and stored at −20° C. Twelve of the 20 samples were from patients who previously had positive test results for at least one antiphospholipid antibody, the initial assay being performed in response to a prior medical or obstetric complication. Two additional patients with normal obstetric histories and no prior testing were also included. The remaining six control specimens were obtained from the antiphospholipid antibody laboratory at the University of Utah and were known to be anticardiolipin antibody positive ($n = 3$), anticardiolipin antibody negative ($n = 2$), or borderline anticardiolipin antibody positive ($n = 1$). After all specimens were obtained, samples were thawed, separated into aliquots, coded, and distributed to all participating centers without patient identification or clinical history. Institutional review board approval was obtained before performance of this study.

Results

All laboratories performed assays for immunoglobulin (Ig) G and IgM anticardiolipin antibodies with an enzyme-linked immunosorbent assay; four of 10 were tested for IgA anticardiolipin antibody as well (Table I). Five of the laboratories requested frozen specimens sent on dry ice, with the others requesting overnight

delivery of fresh sera. Seven laboratories claimed to have standardized their assays with samples derived from the Kingston Antiphospholipid Antibody Study program.[1] Seven of the 10 laboratories reported results in terms of GPL, MPL, and APL units, which correspond to the binding activity of 1 μg/ml of purified anticardiolipin antibody for IgG, IgM, and IgA, respectively[1]; six of these seven also provided qualitative interpretation of positive values as low, moderate, or high. Two laboratories reported positive results as titers without qualitative interpretation, and one reported positive results only as low, moderate, or high.

The questionnaire responses with regard to lupus anticoagulant testing methods are described in Table II. Two laboratories measured partial thromboplastin times, whereas the other three laboratories used viper venom tests or the kaolin clotting time as their primary assay. Three participants required that samples be received frozen, and one specifically requested that the samples be filtered to remove platelets before freezing. Three of the five laboratories were standardized against samples from a different laboratory. Although all tests were bioassays of in vitro clotting function, two laboratories characterized results only as positive or negative and gave no indication of the degree of abnormality.

The clinical histories of the patients from whom samples were obtained are summarized in Table III, along with subsequent treatment and pregnancy outcomes.

The results of serum anticardiolipin antibody testing are now displayed in Table IV. If the presence of any isotype (IgG, IgM, or IgA) at any level is considered a positive result, the number of specimens found to be positive by each laboratory ranged from 5 to 13. For only 5 of 20 specimens (25%) were all laboratories in agreement (i.e., at least one isotype was present or all were absent). For another six patients, all laboratories with one exception were in agreement. For the remaining nine samples tested (45%), there was marked

variation among laboratories regarding the presence of anticardiolipin antibody.

Plasma was available for lupus anticoagulant testing from only 10 patients (Table V). Although fewer laboratories participated, there was less interlaboratory variation with anticardiolipin antibody testing. The results from one laboratory (I), however, were significantly different from the others, with lupus anticoagulant found in 6 of the 10 specimens tested. Among the other four laboratories there was agreement on all specimens but one, for which one laboratory reported the specimen as negative and the other three laboratories detected the presence of lupus anticoagulant.

Comment

During the last decade an increased awareness of potential complications associated with antiphospholipid antibodies has prompted a dramatic increase in testing for anticardiolipin antibody and lupus anticoagulant. Both hospital-associated and commercial laboratories have expanded antiphospholipid antibody testing programs in response to this clinical demand. However, not until 1986 was the possibility of significant interlaboratory variation in antiphospholipid antibody testing formally considered. For anticardiolipin antibody an attempt at standardization of testing was initiated with the first Kingston Antiphospholipid Antibody Study meeting, which resulted in a multicenter comparison of samples.[1] In this study purified anticardiolipin antibody samples from patients with the "antiphospholipid antibody syndrome" were sent to 30 participating university laboratories with instructions on how to prepare the samples for testing. Although there was general agreement in results from samples with high levels of anticardiolipin antibody, considerable variation was found for those sera with lower values. The most recent Kingston Antiphospholipid Antibody Study standardization workshop demonstrated

continued interlaboratory variation among participants for low- and medium-positive values of anticardiolipin antibody.[7] No similar laboratory comparisons have been undertaken for lupus anticoagulant.

Coulam et al.[8] tested samples from 20 women with recurrent spontaneous abortion in four laboratories and concluded that the results of anticardiolipin antibody testing were not reproducible. Only two of eight specimens found to have elevations of anticardiolipin antibody in one laboratory were confirmed as positive in a second facility. These authors questioned the usefulness of a single anticardiolipin antibody test for assessing women with reproductive loss.

Our data also suggest that significant interlaboratory variation exists in anticardiolipin antibody testing. Marked variation in test results among laboratories was found for almost one half of the samples studied. The variation in positivity was not simply a result of differences in determining a mutually agreeable cutoff value (i.e., sensitivity); these differences persisted even when low values were disregarded. Even when there was agreement on the presence of anticardiolipin antibody, there were obvious qualitative differences. We did not assess intralaboratory variation, but prior studies suggest that it may also be a source of substantial variation.[1] These observations suggest that when clinical decisions are based on a single test result detection of anticardiolipin antibody and recommendations for therapy will be highly dependent on which laboratory is used.

Table V. Lupus anticoagulant results

Patient no.	Laboratory A	C	E	F	I
1	−	−	−	−	+
2	−	−	−	−	−
3	+	+	+	−	+
4	−	−	−	−	−

8	−	−	−	−	−
9	−	−	−	−	+
11	−	−	−	−	+
12	−	−	−	−	+

For lupus anticoagulant, interlaboratory comparison demonstrated less variation, a finding consistent with a prior investigation involving hospital laboratories in the United Kingdom.[9] In that study >90% of the laboratories correctly identified negative and strongly positive lupus anticoagulant samples, although sample preparation and assay method used were not standardized.

Clinical consequences could result from a false-positive antiphospholipid antibody result. First, if a positive

result were used to explain a patient's pregnancy losses, other causes deserving further investigation might go unexplored. Second, medical therapy with agents such as prednisone, aspirin, or heparin, if prescribed, would expose the patient to potentially serious risks without therapeutic benefit. The efficacy of these agents has never been tested in a placebo-controlled study in patients with confirmed high levels of anticardiolipin antibody; their therapeutic value is surely in question if the presence of anticardiolipin antibody is uncertain.

The lack of an identified reference laboratory prevents differentiation of discrepant results into false-positive or false-negative ones. We do note, however, that four of our patients with testing discrepancies had normal pregnancy outcomes without therapy for anticardiolipin antibody. Although it is possible that some patients with false-negative or discrepant test results might benefit from empiric therapy, it is more likely that many women are being unnecessarily exposed to the risks of medical treatment.

On the basis of these observations, we advocate the confirmation of a positive result for anticardiolipin antibody in another laboratory before recommendations for therapy are given. This practice would most likely reduce the number of patients being treated, with only a small chance of withholding therapy from a patient who has positive test results in a majority of laboratories. Because many centers have altered and improved their methods over the past 5 years, we also recommend that testing be repeated for patients who have positive results and have been treated for anticardiolipin antibody in prior pregnancies. In contrast, for lupus anticoagulant repeat testing would be less likely to identify any inconsistencies in results.

We thank D. Ware Branch, MD, for providing the control samples for this project.

Discussion

Dr. Edmond Confino, Chicago, Illinois. The association between elevated antiphospholipid antibody, abnormal lupus anticoagulant, and repeated pregnancy loss has been repeatedly documented.[1] However, the best treatment modality remains controversial, and our inability to determine that best treatment modality for patients with this syndrome reflects not only lack of adequately documented prospective, randomized clinical trials but also an inconsistency in the laboratory determination of abnormal levels of anticardiolipin antibody and lupus anticoagulant.[2] This observation prompted the organization of the second international anticardiolipin standardization workshop,[3] which unfortunately was not followed by all clinically involved laboratories worldwide and nationwide.

The authors used anticardiolipin antibody and lupus anticoagulant samples obtained from a single center. These blood samples defined the strongly positive, negative, and borderline values. Although this approach is appropriate, false-positive values may occur in any reference laboratory as well. It is probable that only adaptation of the Kingston Antiphospholipid Antibody Study recommendations will resolve methodologic and reference concerns in those assays.

It is surprising that the interlaboratory differences in the determination of lupus anticoagulant were lower then the differences measured for anticardiolipin antibody. The lupus anticoagulant was measured by different methods such as activated partial thromboplastin time, viper venom testing, and kaolin clotting time. Although it is intuitively expected that differences may be larger with lupus anticoagulant, other authors also reported smaller interlaboratory differences in the designation of strongly positive cases.[4] The search for a reference laboratory determination for lupus anticoagulant is still continuing, and it seems that these bioassays that indirectly measure the ill-defined lupus anticoagulant require further definition and development.[5]

The argument of the authors that positive anticardiolipin antibody and lupus anticoagulant values may potentially interfere with complete evaluation of patients with repeated pregnancy loss is questionable, because it assumes inappropriate medical decision-making. In a similar fashion the argument that false-positive lupus anticoagulant and anticardiolipin antibody determinations will expose patients to unnecessary risky treatments is also debatable, because steroid, aspirin, and heparin treatments are considered experimental and they should be approached and administered as such.

This study further emphasizes the already well-known message that clinical application of lupus anticoagulant and anticardiolipin antibody determinations, and the subsequent treatment of affected patients,

should be regarded as experimental only. Until adequate referencing and method standardization are achieved, physicians are advised to follow the recommendation of the authors to consider positivity only when corroborated by several laboratories and use the information from such testing with cautious critical approach.

Dr. Paul G. Tomich, Maywood, Illinois. Dr. Peaceman and associates have raised the question, "Is there interlaboratory variation in antiphospholipid antibody testing?" Blood specimen results were recorded and the data analyzed for 10 laboratories (five university based and five commercial) and 20 patients (12 of whom previously had positive test results to at least one antiphospholipid antibody, two with normal obstetric histories without prior testing, and six University of Utah control patients).

The study results demonstrate the following:

1. There is significant interlaboratory variation in both anticardiolipin antibody and lupus anticoagulant testing.
2. Lupus anticoagulant results are more reproducible than are anticardiolipin antibody test results.
3. There was excellent correlation with interlaboratory data and the University of Utah control patients.
4. There was minimal interlaboratory variation in those patients with obstetric or medical histories associated with the antiphospholipid antibody syndrome.

These results are not surprising. Since 1983, when Harris[1] introduced the solid phase of the anticardiolipin test, one of the major clinical dilemmas for the practicing obstetrician-gynecologist has been making the laboratory diagnosis of the antiphospholipid antibody syndrome. To that end Harris has made standard positive sera available to several laboratories nationally so that results may be presented in a repeatable quantitative fashion that is referable to an international experience. Unfortunately, as this study demonstrates, some laboratories have not yet standardized their assays with others. Hence physicians are faced with the clinical dilemma of whether to treat even if the patient does not have a history for the antiphospholipid antibody syndrome. This lack of standardization is also a major problem in interpreting clinical data on the antiphospholipid antibody syndrome.

In obstetrics the antiphospholipid antibody syndrome has been associated with a variety of clinical situations: recurrent pregnancy losses, early-onset preeclampsia, stillbirths, intrauterine growth retardation, and other rare obstetric complications.[2-5]

Approximately 2% of low-risk obstetric patients can be identified as having positive results, with poor pregnancy outcomes.[6] Low-positive values are probably not of significance and transient-positive results do occur. IgG antibodies are of more significance than IgM antibody detection.

The implications of substantial variation in laboratory results is obvious. If the result is false positive, overtreatment will occur. If the result is false negative, then undertreatment will occur.

What does this mean to the practicing obstetrician-gynecologist? Dr. Peaceman has suggested that a second anticardiolipin antibody test should be performed. I would suggest that the clinician should use a laboratory where an appropriate immunoassay procedure and report results are presented in a semiquantitative manner with reference to the sera made available by Harris.

I would like to ask Dr. Peaceman three questions:

1. Do you have any information concerning the variation in cost of such testing at each of the laboratories used in your study?
2. Do you have an explanation as to why three of the 10 laboratories have not been standardized by the Kingston Antiphospholipid Antibody Study?
3. In your own referral practice have you developed confidence in your own laboratory, such that you would consider action on those results rather than recommending that another sample be sent out?

Dr. Alan E. Beer, Chicago, Illinois. I would like to ask Dr. Peaceman if he has made a clinical correlation with the laboratory results and if he has also addressed the intraassay and interassay coefficients of variability of the various reporting laboratories. If these are not established, the results that were presented could be meaningless because of lack of this standardization.

Dr. Robert J. Carpenter, Houston, Texas. There's a significant difference in the number of patients stud-

ied in different laboratories, all the way from a low of 40 to a high of 68,400. If one excludes the five lowest laboratories, which all have studies of <2000, is there any closer agreement among the five highest? And for those who have not read it, there's an article in *The New England Journal of Medicine*[1] that puts this whole issue into even greater turmoil.

DR. WASHINGTON C. HILL, Nashville, Tennessee. Your recommendation is that if I send a test off to a laboratory and I get back a positive result, then I need to send it off to another laboratory to see what the laboratory tells me. I'm a little confused with that because then I won't know which test I'm supposed to believe. I think Dr. Tomich's points are well taken. Perhaps, instead of sending the test off to another laboratory, we need to get to know the laboratory where we're having the first test done.

DR. MARVIN L. HAGE, Durham, North Carolina. I would ask the authors if they could present their data taking into account chance agreement. This is an important consideration whether between laboratories or within laboratories. The statistic frequently cited is κ, a statistic that varies between +1 and −1. Second, were any tests of significance used?

DR. JOHN L. AUSTIN, Memphis, Tennessee. I understood the method used in that the specimens were collected, frozen, and then simultaneously thawed and separated into aliquots. What was the variation from collection to the time of testing? I assume that with 10 laboratories there was a transit variable. How stable were these substances in transit, and what were the conditions of transit? Are they similar from laboratory to laboratory?

DR. PEACEMAN (Closing). First, Dr. Confino talked about Dr. Harris's previous studies showing there was a good correlation among different laboratories. What Dr. Harris did report was that when he took samples that were known to be highly positive for anticardiolipin antibody and sent them to academic centers around the world with instructions as to how to prepare the samples, he was able to get a good correlation. In each of his two articles on the subject, however, he cautioned that with low or moderate levels significant variation was seen. We deal mostly with these low or moderate values on a day-to-day basis. So, although he described more correlation than we found, he was also disturbed by the fact that there was less agreement for the samples with low levels of anticardiolipin antibody.

The other issue to remember is that he submitted the samples the way he wanted them run. Our study was very different. We were trying to evaluate current laboratory practice. In other words we submitted the samples in the way each laboratory asked for them and instructed the laboratories to run the samples according to their usual protocols, because that's what happens in everyday testing. We think that as such it better addresses the question as to whether there will be interlaboratory variation among patient care samples.

I agree that part of the discrepancy may be due to differences in calibration among the 10 different laboratories; but once again, this doesn't matter. In terms of our study design, our aim was not to try to correct the laboratories. The goal was to determine whether a sample sent to different laboratories will get different results. To make a decision on therapy on the basis of a single result does not recognize the fact that the issue of positivity may still be in doubt. We think the first step in correcting the problem is indeed recognizing that a problem with testing exists; and for most practicing physicians there is really no recognition that interlaboratory variation exists.

We are glad that Dr. Confino shares our bias against treatment in many of these patients. We are not necessarily advocating treatment if two laboratories are in agreement. Rather, our recommendation is limited to suggesting that if significant interlaboratory variation is identified treatment should not be prescribed until the issue can be clarified.

In answer to Dr. Tomich's question, no, we didn't collect any cost data, although that would be interesting to assess. There are a number of laboratories that are not testing for only one or two antiphospholipid antibodies but running panels testing for more than 20 different antibodies; these tests can be extremely expensive.

We don't know why the laboratories all haven't standardized their protocols. Perhaps the laboratories themselves don't recognize the possibility of interlaboratory variation. Indeed, when some of the directors were contacted, they seemed quite shocked by our results.

Dr. Tomich asked if we trusted the results from our own laboratory. In our hospital samples for anticardiolipin testing are sent out to a commercial laboratory—one of the commercial laboratories tested here. The answer to his question is, no, I don't trust that laboratory entirely. I use the laboratory at the University of Utah for confirming positive results. The last six specimens in this study were obtained from that laboratory, and there was significant agreement among all of the different laboratories for those specimens.

Dr. Beer asked about clinical correlation. With patients who have had a positive test result, we send a second sample off as I described. For those samples that come back with variation in testing results, we suggest that treatment is not necessary. We see such variation in approximately 90% of the patients that are referred to us for testing, and indeed most do well in subsequent pregnancies without therapy. Our clinical suspicion is that most intralaboratory variation represents false-positive rather than false-negative results. Although this is our clinical suspicion, we have not performed a prospective trial to support this contention with strong data.

In terms of intraassay variation, prior studies have shown this to be significant as well. We did not assess this particular issue, but we feel that the interlaboratory variation is significant enough that by itself it calls into question whether treatment is necessary.

Dr. Carpenter asked about excluding the laboratories doing the fewest number of tests. That doesn't solve the problem; unfortunately, it makes it worse. The laboratories with the highest volumes were the ones we thought had the most discrepant results, and that's what we found extremely worrisome. They were the ones doing most of the testing for which recommendations for therapy are being made.

Dr. Hill asked about repeat testing and why two suspicious results might be better than one. Because our clinical experience suggests that discrepant results most likely represent false-positive values, we believe repeat testing will allow many women to avoid the hazards of treatment. Even among the seven laboratories that had claimed standardization with the Kingston Antiphospholipid Antibody Study study, there was significant variation in testing results. Standardizing against Dr. Harris specimens therefore does not guarantee uniformity.

Statistical analysis of this study was not presented. We could not find an appropriate statistical method to evaluate the data for significance of variation. The degree of agreement that was seen is greater than would occur by random chance.

Reproductive outcome in women with recurrent spontaneous abortions of alloimmune and autoimmune causes: Preconception versus postconception treatment

Joanne Y.H. Kwak, MD, Alice Gilman-Sachs, PhD, Kenneth D. Beaman, PhD, and Alan E. Beer, MD

North Chicago, Illinois

OBJECTIVES: The null hypothesis is that treatment of women with recurrent spontaneous abortions with anticoagulation and immunosuppression will not increase the reproductive outcome if it is started preconceptionally.

STUDY DESIGN: Ninety-four women with recurrent spontaneous abortion with autoimmune abnormalities comprised the study group. Group I began autoimmune therapy 48 hours after ovulation: heparin 5000 U twice daily, aspirin 80 mg daily, and prednisone 5 mg twice daily, with an increase to 10 mg twice daily when pregnant. Group II started the same medication after a positive pregnancy test. Group III received no medication. Controls were 19 women with no autoimmune abnormalities. The frequency of reproductive outcome was subject to multiple comparison by the Duncan test.

RESULTS: The percentages of live-born children in groups I, II, and III were 74%, 44%, and 11%, respectively.

CONCLUSIONS: Preconception diagnostic work-up and treatment of autoimmune abnormalities in women with histories of recurrent spontaneous abortion is advocated. (Am J Obstet Gynecol 1992;166:1787-98.)

Key words: Abortion, autoimmune, treatment, preconception

We have previously evaluated both the maternal antipaternal alloimmune and autoimmune status of women with unexplained recurrent spontaneous abortions, women with normal pregnancies, and women who terminate their pregnancies electively early in gestation and have found major differences in the alloimmune and autoimmune status in women with unexplained recurrent spontaneous abortions.[1, 2] In addi-

tion, it has been reported that autoimmunity to certain negatively charged phospholipid molecules can activate phospholipid-dependent coagulation processes in the mother and interfere with phospholipid adhesion molecules thought necessary for cytotrophoblast to syncytiotrophoblast development.[3-5] Women in this category experience a higher incidence of recurrent spontaneous abortion and pregnancy complications. The role that the presence or absence of maternal alloimmunity to paternal antigens and autoimmunity to phospholipid antibodies play in the success or failure of pregnancy is far less well established and still controversial.[6] To address these alloimmune and autoimmune questions we tested women with recurrent spontaneous abortions of unknown cause for alloimmune recognition of paternal antigens and autoimmune responses before their subsequent pregnancy under study. Two hundred seventy women with recurrent spontaneous abortions lacked evidence of prior maternal antipaternal immune recognition and were immunized with paternal or donor lymphocytes. Once adequate levels of antibody were induced, all couples entered a cycle of planned conception. Before attempting pregnancy, 94 consecutive women were delegated to a treatment subgroup. Nineteen women had no autoimmune abnormalities and received no further treatment before or during pregnancy. The remainder of the women with autoimmune abnormalities were prospectively designated to three groups that received (I) preconception treatment starting at the onset of the cycle of conception, (II) postconception treatment with the first positive pregnancy test, and (III) no autoimmune treatment.

We reasoned that this prospective study could provide data that might give insight and answers to a poorly studied and controversial area regarding appropriate therapy for women with recurrent spontaneous abortions. We also reasoned that if antiphospholipid antibodies are capable of altering or unsticking important phospholipid adhesion molecules necessary for placental organ development, a preconception autoimmune treatment may result in a better reproductive outcome than a treatment started after pregnancy is clinically diagnosed or no treatment at all.

Material and methods

Patients. Women with recurrent spontaneous abortions were physician-referred to the Reproductive Immunology Clinic, University of Health Sciences/Chicago Medical School. All were completely evaluated clinically before the immunologic work-up to rule out genetic, structural, endocrine, and infectious causes. Women who had clinically explainable cause(s) for their previous pregnancy losses were excluded. Women who were pregnant at the initial work-up and who had histories of molar pregnancies, therapeutic abortions, and miscarriage after 24-week gestations were excluded from this study. Women with adequate blocking antibody on initial evaluation were also excluded. From these patients 270 women with three or more recurrent spontaneous abortions who showed lack of alloimmune responses were immunized with lymphocytes and comprised the study group. One hundred eleven women in the study group who demonstrated positive antiphospholipid antibodies comprised the treatment group and were prospectively designated to three treatment subgroups before index pregnancy: (I) preconception treatment starting at the onset of the cycle of conception, (II) postconception treatment with the first positive pregnancy test, and (III) no autoimmune treatment. Ninety-four women became pregnant and are reported in this study.

Alloimmune evaluation. Human leukocyte antigen (HLA) tissue typing, mixed lymphocyte culture reactivity, mixed lymphocyte blocking activity, maternal antipaternal antibody assessment by crossmatch with microcytotoxicity, and flow cytometry were conducted as previously reported.[7, 8] The absence of maternal antipaternal T- and B-cell antibodies before immunization (<30% anti-T- and anti-B-cell antibodies) coupled with absent blocking activity (<50%) in mixed lymphocyte culture constituted a lack of alloimmune recognition. Each women in this category was immunized with paternal or nonpaternal donor lymphocytes as previously reported.[9] Postimmunization evaluation documented an adequate response in all.

Autoimmune evaluation. Antibodies to phospholipid and antinuclear antibody were evaluated before immunization and before pregnancy. Once pregnancy was established, these were repeated every 2 weeks. The dynamics of alloantibody and autoantibody levels during pregnancy are not discussed in this article and are the subject of another report.

Antiphospholipid antibody. Antiphospholipid antibodies were tested by enzyme-linked immunosorbent assay.[10, 11] Polystyrene microtiter plates were coated with 30 μl of cardiolipin (45 μg/ml in ethanol) or one of five other phospholipids (50 μg/ml in methanol), that is, phosphatidylserine, phosphatidylinositol, phosphatidylethanolamine, phosphatidyl glycerol, or phosphatidic acid. The plates were allowed to dry overnight at 4° C. After drying, the plates were washed once with phosphate buffered saline, blocked for 2 hours at room temperature with phosphate buffered saline solution containing 10% fetal calf serum, then washed once more. Serum from patients and standards diluted 1:50 in phosphate buffered saline solution containing 10% fetal calf serum were added to the wells. The plates were incubated for 2 hours at room temperature, then washed three times with phosphate buffered saline so-

lution. Fifty μl of indirect antibody (alkaline phosphatase conjugated antihuman immunoglobulin [Ig] G, IgM or IgA) at saturating concentrations were added to the appropriated wells and were incubated for 1 hour. After the incubation the plates were washed three times in phosphate buffered saline solution and 50 μl of *p*-nitrophenyl phosphate (1 mg/ml) were added to each well. After 30 minutes the reaction was stopped by the addition of 50 μl of 3 mol sodium hydroxide to each well. The optical density of each well was determined with a plate reader (Dynatech, Chantilly, Va.) at 405 nm. The Immunosoft program (Dynatech) was used to average duplicate wells and subtract the nonspecific background for each antibody specificity for each class of duplicate wells. Each plate was run with a positive and negative control as standards. Background optical density was determined by running the assay with patient serum diluted 1:50 in 10% fetal calf serum in phosphate buffered saline solution in wells after the same microtiter plates coated with ethanol or methanol but no phospholipids.[12] Cut-off values were determined with sera from 60 nonpregnant healthy women between the ages of 20 and 45. An absorbance ≥3 SD above the mean for that phospholipid, and antibody isotype was considered positive.

Antinuclear antibody. Antinuclear antibodies were measured by indirect immunofluorescence with human laryngeal tumor cells as substrate. Sera were screened for antinuclear antibodies activity at a dilution of 1:40. Those displaying 1+ or greater fluorescence at dilution of 1:40 were considered positive. Positive sera were then retested at dilutions of 1:80, 1:160, and higher when necessary.

Controls. Ninety normal women with documented uncomplicated pregnancies and no history of spontaneous or therapeutic abortions were tested as normal multiparous controls. All control subjects were interviewed, during which time personal and family histories were ascertained. None had an autoimmune disorder, and all experienced the live birth of a healthy baby. Age and gravidity of the control group were matched with those of women with recurrent spontaneous abortions in the study group.

Nineteen women from the lymphocyte-immunized group had no autoimmune abnormalities before and during their pregnancies. They were used as nonautoimmune controls for those immunized women with autoimmune abnormalities.

Medication and obstetric management. Women in group I received preconception treatment with low-dose aspirin, heparin, and prednisone. Patients began autoimmune therapy as follows: aspirin 80 mg daily, prednisone 5 mg twice daily starting day 1 of conception cycle, and heparin 5000 U twice daily administered subcutaneously by self-administration starting 48 hours after ovulation. Prednisone was increased to 10 mg orally twice daily, with a positive β-human chorionic gonadotropin test conducted on days 26 through 28 of the cycle. Group II women received postconception treatment at the time of a positive β-human chorionic gonadotropin test conducted at the end of the cycle of conception. The regimen was aspirin 80 mg daily, heparin subcutaneously 5000 U twice daily, and prednisone 10 mg orally twice daily. Group III women received no autoimmune therapy.

The subsequent prednisone dosage was readjusted according to autoimmune testing every 2 weeks during pregnancy to a maximum dosage of 40 mg per day. The indications for the increased dosage were increasing titers of autoantibodies, antibodies to new epitopes, the reappearance of IgM autoantibodies, or ultrasonic evidence of placental or amniotic fluid compromise. Prednisone was tapered to 10 to 20 mg/day at 24 weeks' gestation and was discontinued at 28 weeks' gestation. Heparin was discontinued at 34 weeks. Aspirin was continued until delivery. All women were monitored in high-risk centers. All women receiving heparin had follow-up clotting studies. Activated partial thromboplastin time and lupus anticoagulant by platelet neutralization procedure[13] and dilute Russell's viper venom time[14] were repeated every 2 weeks during the first trimester and then monthly. Pregnancy losses, fetal growth rates, and fetoplacental Doppler flow kinetics were evaluated monthly by serial ultrasonographic examinations from the first trimester onward. All failed pregnancies were evaluated genetically, immunohistologically, and were tissue-typed (HLA evaluation) by molecular genetic analyses. Analysis of failed pregnancies are the subject of other unpublished reports (Beer and Ober, 1991; Beer and Salafia, 1991).

Statistics. A χ^2 test was used to compare the incidence of autoantibodies and reproductive outcome (success rate, preterm incidence, and large- and small-for-gestational-age incidence); Student's *t* test was used to compare age, gravidity, and parity between study group and multiparous control; and multiple comparison by the Duncan test was used to compare age, gravidity, parity, birth weight, birth height, and gestational age between treatment and nonautoimmune control groups. All analysis was performed with a statistical package for social science version X statistical package on a Dell 386 (Austin, Texas) system computer. Differences were assumed to be significant whenever $p < 0.05$.

Results

Autoantibody profile. The age and gravidity of recurrent spontaneous abortion women and multiparous normal control women were comparable. The ages were 33.3 ± 4.6 and 32.6 ± 4.0, respectively. The incidence of antiphospholipid antibodies in recurrent

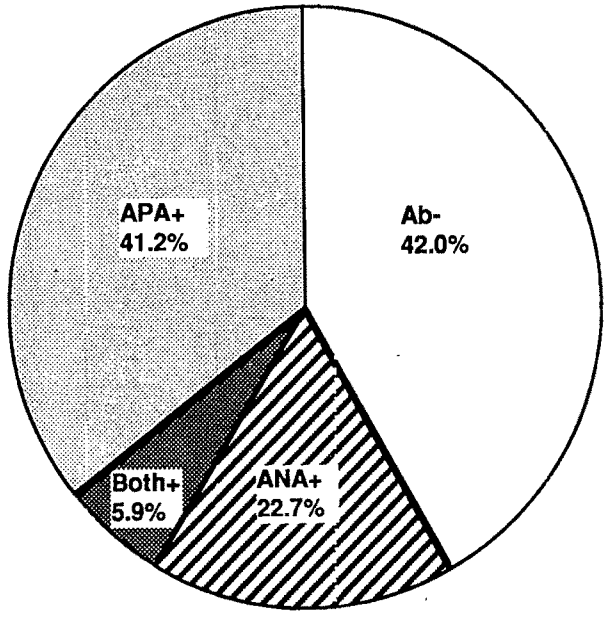

Fig. 1. Autoimmune abnormalities in women with recurrent spontaneous abortion ($n = 270$). *Open area,* women with neither antiphospholipid antibodies *(APA)* nor antinuclear antibodies *(ANA); stippled area,* APA-positive women; *Striped area,* ANA-positive women; *Shaded area,* APA-positive and ANA-positive women.

spontaneous abortion patients (41.2%) was significantly higher than that of the control group (18%) ($p < 0.05$). Incidence of antinuclear antibodies positivity was different between recurrent spontaneous abortion patients (22.7%) and the control group (12.5%) ($p < 0.05$). The autoantibody profiles of the recurrent spontaneous abortion patient population are shown on Fig. 1. When the incidence of positive antiphospholipid antibodies of recurrent spontaneous abortion women is analyzed by the number of previous abortions, there is a stepwise increase in positive antiphospholipid antibody incidence observed with the increasing number of previous spontaneous abortions, but not in age-matched multiparous control by gravidity (same as the number of live-born offsprings) (Fig. 2). Antinuclear antibody incidence showed similar tendencies (Fig. 3).

Alloimmune and autoimmune status of women in treatment and control groups. Age, gravidity, parity, and number of spontaneous abortions of treatment and nonautoimmune control groups are listed in Table I, and there are no differences between groups. Table II provides data to show there were no differences in the alloimmune status of women in any treatment or nonautoimmune control group preimmunization or postimmunization with lymphocytes. All demonstrated an adequate alloimmune response post lymphocyte immunization. Table III lists the autoimmune status of women in all groups. There were no statistically significant differences. This equality between treatment groups provides assurance that the reproductive outcome differences were not explained by more or less severely affected women in any one group.

Reproductive outcome. Pregnancy outcome in all treatment and nonautoimmune control groups is described in Table IV. The nonautoimmune control group that received lymphocyte immunization had a live-birth rate of 84.2%. This is significantly different when compared with the postconception treatment group ($p < 0.05$) and the no-medication group ($p < 0.00001$). The preconception treatment group (group I) had a significantly superior reproductive outcome when compared with the postconception treatment group (group II) ($p < 0.05$) and the no-medication group (group III) ($p < 0.00001$). The postconception treatment group (group II) had a better outcome than the no-medication group (group III) ($p < 0.05$).

Length of gestation. The nonautoimmune control group showed significantly longer gestations than all other groups with autoimmune abnormalities (Table IV, Fig. 4). The length of gestation is increased with autoimmune medication and early onset of medication. When the length of gestation in patients who aborted again after all types of therapy were compared, no significant differences were seen (data not shown). The preconception treatment group infants demonstrated a significantly higher incidence of prematurity than nonautoimmune control group babies ($p < 0.005$). The postconception treatment group also showed a higher incidence of prematurity ($p < 0.05$) when compared with the same nonautoimmune control. In the no-medication group only two women delivered; both infants were premature (Table IV).

Other clinical parameters. Birth weights of infants from all treatment groups were significantly lighter than those of the nonautoimmune control group. No significant differences were seen in babies of any group regarding length, Apgar scores, incidence of intrauterine growth retardation, and largeness for gestational age (Table V). Complications are listed in Table VI; there were no pregnancy complications that appeared unique to any group.

Comment

Our study demonstrates that spontaneous recurrent pregnancy losses are associated with an increasing incidence of autoantibodies to nuclear antigens and phospholipid antigens. The incidence is 34% in women with three recurrent spontaneous abortions and 50% by the fifth pregnancy lost, respectively. This incidence is not seen in control healthy multiparous women or women having their pregnancies electively terminated.[1] There are several possibilities regarding initiation of the au-

toimmunity in patients with recurrent spontaneous abortions: a pregnancy that does not achieve alloimmune protection may stimulate autoimmune response in its mother upon its demise; or in some pregnancies HLA–closely matched couples are autoantigenically unacceptable, that is, they have cell surface molecular features that are known to be associated with autoimmune disorders. In this circumstance they are lost be-

fore they establish alloimmune recognition. It is quite clear that the establishment of alloimmune recognition in women with autoantibodies to nuclear and phospholipid antigens before their next pregnancy without any further autoimmune treatment is associated with a 90% failure rate. A molecular genetic analysis study of liveborn children is also underway to determine whether surviving children have cell-surface features that cause them to be at a high risk of developing an autoimmune disorder. This study shows that paternal or donor lymphocyte immunization offered to women with recurrent spontaneous abortion is associated with a very high incidence of subsequent pregnancy failure if autoimmune serologic abnormalities are also present in the mother. Our center has consistently tested for both alloimmune and autoimmune abnormalities in women with recurrent spontaneous abortion and is the first to report this finding. The widely varied success rates in lymphocyte-treated women versus control women in centers using immunotherapy for recurrent spontaneous abortion[9, 15] must now be reevaluated on the basis of these new findings. Such collaborative studies are now in progress, and double-blind studies are beginning (unpublished report, Ober and Beer, 1991).

It is of major interest that women with serologic autoimmune abnormalities who have received preconception therapy had significantly better pregnancy outcomes than those whose therapy was started with the first positive β-human chorionic gonadotropin (4 to 5 weeks of gestation at the latest) and with those who

received no autoimmune therapy at all. If autoimmune therapy is truly associated with this difference, it suggests that immune processes operate far earlier than we had previously suspected. There are several possibilities. There is a large body of data surfacing that autoimmune responses to adhesion molecules that are putatively necessary for the events of implantation and placentation may interfere with these processes. The phospholipids of adhesion molecules that have been studied and shown to be related to placentation are phosphatidylethanolamine and phosphatidylserine. These phospholipids have been shown to serve as adhesion molecules for smooth-muscle and fibroblast cells to fuse and form syncytia.[3, 4] These data suggest that phosphatidylethanolamine and phosphatidylserine molecules may serve in the formation of syncytiotrophoblast from cytotrophoblast. When the configuration of the adhesion molecules are changed experimentally by creating a hexagonal II phase (reversed vesicles with the glue inside them) that is reported to be immunorecognizable, the process of syncytia formation can be stopped.[3, 4, 16] The high incidence of autoantibodies in women with recurrent spontaneous abortion and endometriosis[17] suggests that they are causally related

Table V. Clinical outcomes of pregnancies from treatment groups and nonautoimmune control groups

Clinical outcome	*Preconception therapy (Mean ± SD)*	*Postconception therapy (Mean ± SD)*	*No therapy (Mean ± SD)*	*Nonautoimmune control (Mean ± SD)*	*p Value*

Osteoporosis	1	—	—	—

to early placental organ failure by causing abnormal phase and changes. Studies are now in progress by our group to address this possibility.

The superior success rates of pregnancy experienced by women who were offered preconception treatment must be tempered with the observed and potential complications of this therapy. Although heparin does not cross the placenta[18] and would not be expected to have an adverse effect on the fetus, its therapeutic application is associated with some adverse outcome in approximately one third of pregnancies.[19] In therapeutic doses it may induce osteoporosis.[20] However, the high rate of adverse fetal-neonatal outcome in the heparin-treated patients could be explained by the presence of maternal comorbid conditions.[21] Recently it has been reported that the rate of prematurity, abortion, stillbirth, neonatal death, and congenital abnormality of individuals who received a high-dose heparin regimen throughout pregnancy were similar to in the normal population.[22] In this study patients received a mini-dose of heparin until 34 weeks' gestation. Three patients (3.9%) in the preconception treatment group had mild vaginal bleeding episodes during the course of heparinization. It has been reported that 2% of the patients who received heparin during pregnancy had significant antepartum vaginal bleeding.[22] An incidence of heparin-associated thrombocytopenia is reported as 10%[23]; however, in our series no patient had thrombocytopenia while on heparin. One patient with the preconception minidose heparin treatment had osteoporosis. We recommend bone densitometry after delivery to further evaluate this risk.

Low-dose aspirin therapy is reported to be safe for the fetus and mother. A dose of 60 to 80 mg of aspirin daily during pregnancy selectively inhibits maternal platelet cyclooxygenase without affecting neonatal platelet aggregation or pulmonary circulation. Maternal platelet thromboxane B2 production in response to adenosine diphosphate or collagen was reduced 98% by the 80 mg dose after 1 week of therapy.[24] The superior success rate observed with preconception treatment may be partly explained by this.

What constitutes an autoimmune abnormality in women with recurrent spontaneous abortion is not yet defined or agreed on. However, there is evidence that trophoblastic antigenic stimuli during pregnancy may induce autoantibodies, including antiphospholipid antibodies.[25] How often the abnormalities discussed in this study are seen in normally reproducing women before and during pregnancy is unknown and is currently under study by our group. It is becoming clear that recurrent spontaneous abortion women with autoimmune abnormalities and no symptoms of autoimmune disease who have entered our study early and have been

observed for more than 12 years have not had autoimmune symptoms or diseases. Studies are in progress to determine whether autoimmune preconception therapy alone without any lymphocyte immunotherapy, allows more appropriate fetal-embryonic trophoblast antigen presentation in the prospective mother by the spontaneous development of the correct alloimmune recognition response that attends a normal pregnancy. This study applies most specifically to women who lose embryos repeatedly and very early after in in vitro fertilization programs and embryo transplantation. Multicenter prospective clinical studies are needed regarding the immune consequences to the mother of recurrent spontaneous abortion and its appropriate therapy.

Discussion

Dr. James R. Scott, Salt Lake City, Utah. Potential immunologic aspects of recurrent spontaneous abortion is a timely topic that has been well publicized in both the medical and lay literature, but it remains a confusing and controversial area clearly in need of well-controlled studies. The purpose of this study was to determine whether treatment early in pregnancy with aspirin, prednisone, and heparin was beneficial in recurrent abortion patients of presumed autoimmune causes. In my opinion the present study requires cautious interpretation for several reasons.

A battery of autoimmune assays was performed on each patient (six antiphospholipids, IgG, IgM, IgA subclasses of each, and an antinuclear antibodies), and at least one positive test was presumably the basis for an autoimmune diagnosis. However, the actual results of the tests are not given. If a mean +3 SD as normal, there is a 17% chance that at least 1 of the 19 laboratory tests will be abnormal but clinically insignificant in any given normal individual. For example, there is a 10%

to 20% false-positive rate of antinuclear antibodies in normal pregnant women.[1] To my knowledge the only proven autoantibodies associated with recurrent pregnancy loss are lupus anticoagulant and anticardiolipin, and elevation of IgM and IgA values may be nonspecific and unrelated to reproductive problems. We have found that using +3 SD as the cutoff between normal and abnormal levels for anticardiolipin and other antiphospholipid antibodies yields an unacceptably high number of weak positives and overdiagnosis of this condition in women who actually have successful pregnancies without treatment.[2] I suspect that these factors contributed to the overall 68% incidence of autoantibodies in this population of recurrent spontaneous abortion patients because this is much higher than has been reported by other groups.

Any study of pregnancy-loss patients should clearly define the patient selection criteria to show that the groups are truly comparable. How were the patients randomized, and was the study blind? If not, the potential for bias is high and jeopardizes the results and conclusions. I was unable to determine how ovulation was detected, how it was decided which patients would be placed in each group, over what period of time the study occurred, what physicians participated, the total number of patients treated who did not conceive, how long treatment was continued in those women, and how accurate follow-up information was obtained. If heparin were started 48 hours after ovulation, this treatment for group I was not preconceptual but rather preimplantation. It is unclear to me exactly how the drug regimen was monitored in each patient, the criteria for raising the prednisone dose to as high as 40 mg per day, and what the dose relationship was to the pregnancy outcome. The cost of these diagnostic tests is significant, and repeating all tests every 2 weeks would be very expensive from a practical standpoint. Anticardiolipin levels are often not altered by treatment, and we have found little relationship between live birth rates and lupus anticoagulant levels. It also seems doubtful that meaningful Doppler flow kinetics could be monitored in the first or early second trimester, and no data are shown.

On the basis of their results, the authors advocate preimplantation treatment with aspirin, prednisone, and heparin. However, their 73.8% success rate is no higher than that reported by a number of investigators for well-defined antiphospholipid syndrome patients with recurrent pregnancy loss who began treatment with low-dose aspirin and either prednisone or heparin alone after pregnancy was diagnosed.[2-4] If both of the authors' treatment groups are combined, the live-birth rate is only 62%, raising the possibility that this drug combination is actually less effective. According to our statistician, χ^2 tests should not be used when the numbers are too small, as they are in some cases. For example, mean values and statistical comparison of the length of gestation, birth weight, height, and Apgar scores in Tables IV and V are rather meaningless when there are only two patients in the group with no treatment.

The authors rightly comment on potential serious complications when corticosteroids and heparin are combined during pregnancy. We have recommended against this treatment in the absence of evidence that it is better than prednisone or heparin alone, and we know of several patients treated with both drugs who developed severe osteopenia and vertebral or hip fractures. Therefore I believe that the effectiveness and safety of this regimen must be clearly shown before it is widely adopted. Finally, because this study as experimental, was it approved by the Institutional Review Board, and did the patients pay for these tests and treatments?

Dr. Beer and his colleagues have been major contributors to innovative research in reproductive immunology over the past decades. I enjoyed reading the paper and encourage them to continue their investigation of recurrent pregnancy loss.

DR. JOHN G. GIANOPOULOS, Maywood, Illinois. I would like to thank the Association for the privilege of discussing this most interesting and timely article. It is estimated that 20% to 30% of all recognized pregnancies end in spontaneous abortion. Patients experiencing ≥3 repetitive losses with no live-born children account for 1% of all pregnancies. These unfortunate pregnancy outcomes may have a number of causes. Anatomic malformations, hormonal deficiencies, infectious pathogens, parental genetic abnormality, and immunologic causes have all been implicated in this pathologic reproductive entity. Recently there has been much research directed at immunologic causes for repetitive pregnancy loss, particularly the phospholipid antibody syndrome. Dr. Kwak et al. have focused their work on those patients suffering immunologic reproductive failure.

All patients entered into their analysis were screened for all the known causes for recurrent abortion, and only those patients with immunologic abnormalities were included in this study. Patients in this study were all determined to have alloimmune abnormality with low levels of paternal blocking antibody. They were all treated with leukocyte immunization. The experimental group consisted of 94 patients with autoantibodies

to phospholipid. Patients were assigned to prepregnancy therapy, postconception therapy, and no-therapy groups. All groups were similar in their demographics, with similar reproductive characteristics. Patients receiving prepregnancy therapy with prednisone, aspirin, and heparin demonstrated a significantly better outcome of live-born neonates than the other groups, 73% versus 44% and 11%, respectively.

This study raises a number of interesting questions. Is there an advantage to successful outcome in pretreating patients with thrombotic and immune therapy rather than initiating therapy at the onset of a recognized pregnancy? On review of the existing literature, all with postpregnancy initiation of therapy, there appears to be no advantage to prepregnancy therapy because the successful outcome equals 80%, which is not significantly different from Dr. Kwak's pretreatment group. In fact, the current study's postpregnancy treatment group demonstrates a significantly different outcome than would be expected from previously published reports (Table I). The previously reported series were not controlled for alloimmune causes. Could this explain the differences in outcomes? Each patient in Dr. Kwak's analysis, however, was treated for alloimmune deficiency and demonstrated normal blocking antibody. This leads me to assume that alloimmune incompetence cannot explain this obvious difference.

It is known that steroids may lead to adverse reactions related to the length of exposure; if it is assumed there is no benefit from pretreatment, this strategy may unnecessarily expose patients to potentially dangerous therapy for longer than is needed. The authors report no adverse reactions to therapy. However, in analyzing their data, I note that complications of gestational diabetes and pregnancy-induced hypertension (both steroid-related complications) were higher in the pretreatment group 4 (12.9%) of 31 versus 1 (6.7%) of 15 in the postpregnancy treatment group. Could the longer exposure to steroids have led to this observation? The authors do not report the average time interval from the initiation of therapy to the onset of pregnancy in the prepregnancy therapy group.

Patients with recurrent abortion caused by antiphospholipid antibodies undergoing therapy have been reported to show a 50% to 60% incidence of prematurity complications. The data in this study also demonstrate this observation, with a 64% prematurity rate in the treated groups. It is important to keep this in mind when caring for these patients and to take precautions in management for the potential of preterm labor.

I pose the following questions to the authors:

1. The groups included in the analysis are of unequal size. How were patients assigned to therapeutic groups? Were patients randomly assigned, or were clinical factors used in assignment to experimental groups? Could this have affected outcome?
2. What factors, if any, could explain Dr. Kwak's observation of a poorer outcome in the postpregnancy therapy group when compared with previously published reports?
3. What was the average interval from the onset of therapy in the prepregnancy treatment group to the onset of pregnancy? Do the authors feel that this interval explain the slightly higher incidence of steroid-related complications in the prepregnancy treatment group?
4. Do the authors believe that the antithrombotic effect of salicylate and heparin has a critical effect and that prepregnancy steroid therapy may not be needed?

Future research will be needed to answer the question as to whether pretreatment with aspirin or heparin alone improves outcome.

Dr. Michael R. Caudle, Knoxville, Tennessee. Why do the authors continue to do HLA typing to diagnose

alloimmune failure when it does not clearly identify a population that has pregnancy loss?

Dr. Kwak (Closing). This preconceptional treatment study for women with recurrent spontaneous abortion was initiated because preconception therapy in autoimmune infertile women who became recurrent spontaneous abortion patients through in vitro fertilization or gamete intrafallopian transfer were having a better reproductive outcome than the classical recurrent spontaneous abortion patients who heretofore had therapy initiated at the onset of a positive β-human chorionic gonadotropin. This is not a double-blind study. Sequential patients were allocated into the three different subgroups after a comprehensive physician-patient consultation to ensure that patients in the various subgroups were comparable regarding age, gravidity, and laboratory abnormalities.

β-human chorionic gonadotropin testing was used to determine the onset of pregnancy and the onset of postconception therapy. This was done from day 25 through day 30. Women were instructed to begin therapy at the time of a positive β-human chorionic gonadotropin.

Ninety-four of 111 patients in this study established their pregnancies within 6 months. The remaining 17 did not establish a pregnancy during the study period. The age, gravidity, and alloimmune and autoimmune parameters in these women were not significantly different from those who established pregnancies.

Doppler ultrasonographic evaluation was done on all women sequentially during pregnancy. These findings are the subject of a separate report.

The enzyme-linked immunosorbent assay is used to detect antiphospholipid antibodies. Sixty healthy, nonpregnant women were used as controls. Nonspecific background bindings were subtracted. The value at mean ± 3 SD corresponds in optical density to the moderate positivity reported by Harris using control sera provided by him. Because patients are screened every 2 weeks and sera from prior testing is repeated with subsequent testing, we have reduced our interassay coefficients of variability to a low level, which provides assurance that the 3 SD value is reliable and real.

In a review of the literature regarding osteoporosis and heparin therapy, 119 patients are available for analysis. No case of heparin-induced osteoporosis was found when the dosage was ≥10,000 U per day. Six of 10 women receiving a therapeutic heparin dosage had osteoporosis. All of our patients received 10,000 U of heparin daily. We report one case of mild osteoporosis that resolved postpartum. This patient experienced a 25% density loss. She is now pregnant a second time. We advocate bone densitometry assay for women receiving both heparin and prednisone, not minidose heparin alone.

Previous reports regarding human leukocyte antigen sharing between recurrent spontaneous abortion couples are still controversial. Maternal antipaternal antibody before and after lymphocyte immunization correlates with the number of HLA antigens shared, specifically at HLA-DR and HLA-DQ. The greater the numbers shared, the lower the postimmunization responses and the greater number of pregnancy losses after immunization. In couples with excessive DR/DQ antigen sharing we found the reproductive outcome to be poor when compared with couples who do not share these antigens. In addition, when donor immunization was indicated, tissue typing was done for selection of the most appropriate donor.

Lack of alloimmune recognition before and after paternal or donor lymphocyte immunization is defined by a flow cytometer crossmatch developed by us. This crossmatch is very sensitive and can document a maternal antipaternal anti–T- and –B-cell response very early in pregnancy. The crossmatch by microcytotoxicity will be positive in only 50% of these pregnant women and is a test not sufficiently sensitive to be useful clinically. In a study by Kiprov,[1] 72 women with successful pregnancies were compared with 141 women with recurrent abortions and with 72 heterosexual males whose cell and sera were paired in this assay. Pregnant women had crossmatch values six times greater than women with recurrent spontaneous abortion or the male controls.

I am glad to have received so many interesting and challenging questions. This topic is a clinical one of continuing controversy. Fortunately, newly developed immunologic assays allow a critical analysis of alloimmune and autoimmune responses during pregnancy. It is becoming clear that a fetus must signal the maternal immune system to deal with it in a manner unlike that involved in an infectious response. It also is becoming clear that fetuses who do not stimulate an alloimmune response in their mothers are subject to the elicitation and expression of subtle autoimmune responses that may be detrimental to placental development. Certainly double-blind multicenter trials are now necessary in the further dissection of the problem of recurrent spontaneous abortion.

The Green Bay cesarean section study

II. The physician factor as a determinant of cesarean birth rates for failed labor

Robert K. DeMott, MD, and Herbert F. Sandmire, MD
Green Bay, Wisconsin

OBJECTIVE: Our study was designed to develop a profile of specific labor management characteristics generally used by physicians with low versus those with high rates of cesarean sections in the care of nonprogressive labor in nulliparous patients.
STUDY DESIGN: A 4-year retrospective data set was used to analyze all patients with nonprogressive labor cared for by 11 board-certified obstetricians and gynecologists practicing full-time at two Green Bay hospitals. Variations in labor management are analyzed and tested for their effect on the rate of cesarean section for failure of labor to progress.
RESULTS: Cesarean section in nulliparous women for nonprogressive labor varied from 4.3% of all deliveries in the low group to 12.3% in the high group. Through multivariate analysis we developed a profile of specific labor management characteristics used by physicians with low versus those with high rates of cesarean section.
CONCLUSION: These techniques can be used to definitively identify management strategies that result in a decrease in cesarean rates for nonprogressive labor. (AM J OBSTET GYNECOL 1992;166:1799-1810.)

Key words: Cesarean section, nonprogressive labor

The United States cesarean section rate has received increasing attention and concern after its rise from 5% in the early 1970s to 15% in the late 1970s and approximately 25% in 1988. The current rate is viewed as a national disgrace by some[1] and as about right by others,[2] demonstrating the divergence of opinion regarding the optimal cesarean rate. Increasing concern with a 15% cesarean rate led to the convening of a consensus development conference in 1980. The major conclusion of the conference members was that the rise of the cesarean rate to 15% was a matter of concern and that the goal of clinical obstetricians everywhere should be to contain this trend while maintaining good maternal and perinatal outcome.[3] The ensuing further increase demonstrates the difficulty encountered in translating research findings, guidelines, and recommendations into clinical practice.

We have been concerned about cesarean rates associated with "modern" perinatal care. In our previous Green Bay cesarean section study[4] individual physician cesarean rates ranged from 5.6% to 19.7%. Cesarean rates for physician groups ranged from 9.8% to 18% with proportional differences for the four major indicators for cesarean section: repeat cesarean, failure of labor to progress, breech presentation, and fetal distress. The variances in cesarean rates among individual and groups of physicians were not attributable to patient obstetric risk factors, socioeconomic status, service status, or duration of the physician's practice. Higher cesarean rates did not result in better newborn outcome. Individual physician practice style was the only apparent determinant of cesarean rates. It was concluded that the current cesarean rates could be substantially reduced without sacrificing fetal and newborn safety.

Presently we are attempting to identify those specific variations in practice style for each of the major indicators for cesarean section that result in variable cesarean rates in similar patient populations. This report analyzes those variations in the management of nonprogressive labor (dystocia).

Repeat cesarean section is the most common indication for all cesarean deliveries in the United States. Nonprogressive labor is the most common indication for cesarean section in nulliparous women. It is apparent that many physicians do not encourage women who have experienced nonprogressive labor initially to attempt a vaginal birth in subsequent pregnancies. Thus this self-perpetuating cycle, beginning with ce-

sarean section for failure to progress (dystocia) in the nulliparous labor, should be averted, where possible, to reduce the rates of cesarean section.

Material and methods

For this study all cesarean deliveries performed for nulliparous, term, and vertex presentation pregnancies were analyzed when the primary indication for cesarean section was listed by the obstetrician as either "failure to progress" or "cephalopelvic disproportion"; our 3-year review of all cesarean deliveries from 1986 to 1988 was used as the data base.[4] We added a fourth year of data, 1989, collected in the same fashion. Also included in this 4-year analysis are all women laboring for the first time after one or more previous cesarean sections. The study included all such cesarean sections performed by 11 board-certified obstetricians and gynecologists practicing exclusively and full-time at two Green Bay hospitals.

A second study group included the same detailed analysis of all operative vaginal deliveries (forceps or vacuum extractions) for similar patients done by the same physicians when the second stage of labor was prolonged for >2 hours or the physician listed the indication as "failure to progress."

Randomized controls consisted of spontaneous vaginal deliveries from the 4-year analysis (nulliparous, term, and vertex presentations). For each cesarean delivery the next spontaneous vaginal delivery was chosen as a control.

From the 9480 deliveries occurring during the 4-year data collection period, we identified 766 deliveries meeting those criteria and divided them into the following groups: group 1, cesarean deliveries for nonprogressive labor, $n = 212$; group 2, forceps or vacuum deliveries for nonprogressive labor, $n = 143$; group 3, spontaneous vaginal deliveries (control), $n = 411$.

Each study group was analyzed for patient characteristics that influence cesarean delivery rates to ascertain distribution among the 11 physicians (Table I). An estimation was made for each physician of the percentage of his or her practice that consisted of nulliparous, term, vertex pregnancies based on the profile provided by the randomized control vaginal deliveries and the known values in their entire cesarean section population. Thus we could calculate for each physician a rate of cesarean section for failed labor in nulliparous, term, vertex, singleton pregnancies (Table II).

The physicians were placed into low, medium, and high groups based on their rate of cesarean delivery for failure to progress (Table II). Also listed are comparable rates of operative vaginal deliveries. For comparison, Table III lists the overall cesarean rate and the number of repeat cesarean deliveries for each physician. The possible variations in labor management by the groups of physicians, which are analyzed in detail, are listed in Table IV.

These maternal and neonatal outcomes were analyzed: 1- and 5-minute Apgar scores, need for resuscitation, neonatal intensive care unit admissions, need for ventilatory support, morbidity, mortality, and length of stay.

We analyzed the data by the use of "Proc freq" and "Proc GLM" in the Statistical Analysis Systems. Relevant continuous variables were subjected to two-way analysis of variance to examine interaction between physician groups and mode of delivery. Where the data were frequencies, two-way tables of frequencies were analyzed by χ^2. The Wilcoxon test of significance was used for nonparametric data. Separate analyses were performed for cesarean sections (group 1), forceps and vacuum extractions (group 2), and spontaneous vaginal deliveries (group 3).

Results

Overall cesarean rates of individual physicians varied from a low of 5.0% to a high of 19.5% (Table III) with a range of 9.4% to 16.4% by groups of physicians. Cesarean section for failure to progress varied from 2.7% of all primary deliveries to 16.0% for individual physicians with a range of 4.3% to 12.3% by groups of physicians (Table II). Socioeconomic characteristics (Table V) did not vary between physician groups or mode of delivery. The one exception, with no apparent explanation, involved a greater percentage of Lamaze-trained patients in the group requiring forceps- or vacuum-assisted vaginal deliveries.

Maternal and fetal biologic characteristics (Table VI) did not differ between physician groups. Of greatest importance, the average newborn birth weights and head circumferences were the same among physician groups. As expected, all biologic characteristics varied significantly between modes of delivery. Cesarean de-

liveries included larger newborns with larger head circumferences born to shorter and heavier women at greater gestational ages.

Epidural use is very uncommon in Green Bay. Only five laboring patients received intrapartum epidural anesthetics, and three of them had failure to progress and underwent cesarean delivery.

Significant differences were noted between physician groups in the peak dose of oxytocin use (Fig. 1) and the cervical dilatation at which both oxytocin was initiated and the cesarean section was ultimately performed (Table VII). In a significantly greater percentage of patients in the low group complete dilatation was achieved before cesarean delivery, and physicians in the low group allowed significantly longer second-stage labors (although this contribution was primarily in patients who were ultimately delivered by forceps or vacuum). Physicians in the low group gave oxytocin augmentation to a significantly greater percentage of their spontaneous labor patients before they resorted to cesarean section for nonprogressive labor (82% vs 58% for the combined medium and high groups, $p < 0.01$). Cephalopelvic disproportion or suspected macrosomia were commonly cited by high and medium cesarean rate physicians when oxytocin augmentation was omitted in their management of nonprogressive labor. In the low group only 6 of 34 spontaneously laboring patients did not receive oxytocin before undergoing cesarean delivery. Also noted was a tendency ($0.05 < p < 0.10$) for physicians in the low group to

Table IV. Variables studied in labor management

   a. Cesarean delivery
      Morning (6 AM to noon)
      Afternoon (noon to 6 PM)
      Evening (6 PM to midnight)
      Night (midnight to 6 AM)
   b. Admission
   c. Rupture of membranes
2. Induction of labor by artificial rupture of membranes
3. Oxytocin
   a. Cervical dilatation at time of augmentation
   b. Maximum dose
   c. Duration of use
4. Use of epidural anesthesia
5. Frequency of indicated forceps or vacuum delivery
6. Cervical dilatation at time of cesarean section
7. Duration of first stage of labor at time of cesarean section
8. Duration of second stage of labor at time of forceps or vacuum delivery
9. Duration of second stage of labor at time of cesarean delivery

administer oxytocin for longer periods of time and to allow a greater duration of membrane rupture before delivery (Table VII).

There were no significant differences between physician groups in the percentage of patients with labor induced, the length of first-stage labor, or the time of day cesarean delivery was performed.

For neonatal and maternal outcomes, logistic regression demonstrated no differences in Apgar scores (Table VIII), length of stay, neonatal intensive care unit admission, respiratory support, or significant morbidity between physician groups. There were no neonatal or maternal deaths in this study population. Maternal morbidity was quite rare with no differences between physician groups. All six cases of endometritis occurred in patients with cesarean section.

Comment

O'Driscoll et al.,[5] at the Dublin Maternity Hospital, demonstrated that active management of labor enables them to safely minimize the need for cesarean section for the diagnosis of dystocia. Turner et al.[6] reported similar results, with a cesarean rate of 5.6% among nulliparous patients given an oxytocin regimen of 6 to 40 mU/min, with increases at 15-minute intervals. Fraser et al.[7] found a substantial increase in cesarean births during convenient evening hours; however, when corrections were made for the unexpected temporal variations in the proportion of patients in prolonged labor, the disproportion was minimal, accounting for only 15% of the cesareans for dystocia. Neuhoff et al.,[8] DeRegt et al.,[9] and Taylor,[10] as well as others, has demonstrated that private patients in university teaching hospitals are subjected to cesarean section more readily for failure to progress in labor than are "clinic" patients. Gould et al.[11] noted a 76% higher cesarean rate when considering patients with high versus low family incomes. Substantially higher cesarean rates have been reported with the use of epidural anesthesia.[12]

Many authors have observed the lack of consistency between research findings and clinical practice. Lomas et al.[13] answered their question, "Do practice guidelines guide practice?" in the negative. Commenting on the poor relationship between practice behavior and published literature, Greer[14] demonstrated that the need for change must come at the local level rather than externally. Similarly, Stafford[15] believes that " . . . formal programs aimed at modifying practices within individual hospitals appear to be the most successful . . . " for controlling rising cesarean rates. Porreco,[16] also emphasizing the local level, recommended the following for each hospital: an individual physician designated as the cesarean section monitor, coalitions to manage labor, and tort reform measures of proved effectiveness similar to those enacted in California.

All of these liken the high cesarean rate to Mark Twain's comment on the weather: "Everybody talks about it, but nobody does anything about it." Actually, the rising concern has galvanized some individuals and groups into action, which is currently in the planning stages with no results to date. Examples include a joint New York task force[17] consisting of members of the New York State Health Department, the American College of Obstetricians and Gynecologists, and the Hospital Association of New York State. Similarly, the Maryland Hospital Association has embarked on a research project: "Evaluating the appropriateness of care: a study of cesarean section rates."[18]

To reduce the cesarean rate in nonprogressive labor, we must identify those management techniques that are effective in achieving that goal. Our data support the notion that physicians may achieve lower rates of cesarean section for failure to progress (4.3% vs 12.3%) by giving augmentation to more patients in spontaneous labor and giving higher doses of oxytocin for longer periods of time but waiting until the truly active phase of labor (later cervical dilatation) before initiating oxytocin or resorting to cesarean section. High and medium cesarean rate physicians were reluctant to give augmentation to some patients because of perceived cephalopelvic disproportion or macrosomia, in spite of the inability to diagnose cephalopelvic disproportion without an adequate trial of labor[19, 20] and the known

inaccuracy of fetal weight[21] estimations, whether by ultrasonography or clinical palpation. This reluctance may have been fostered by the *ACOG Technical Bulletin* on "Induction and augmentation of labor"[22] in force during most of the period of this study, to wit: "After cephalopelvic disproportion and macrosomia have been ruled out. . . ." Perhaps the time has come to abandon the term cephalopelvic disproportion as it relates to nonprogressive labor. Certainly the extensive experience with vaginal birth after cesarean section[23] demonstrates the futility of thinking that we can identify that entity. Our findings agree with a recent statement made by Porreco[16] that in many cases failure to progress means failure to wait. There is ample suggestion from our data that the lower cesarean rate physicians are more patient in their management of slowly progressing, nulliparous patients. These management techniques, which reduce the need for cesarean delivery, can be utilized in similar patient populations with equal newborn outcomes.

Given the analysis of our data leading to these conclusions, we ask ourselves: Can it be that simple? Do "modern" oxytocin dose regimens generate "modern" cesarean delivery rates? Preliminary to our analysis of historic information regarding cesarean rates for oxytocin, we make a presumption that the pelvic capacity of women in the United States has not decreased and that newborn size has not significantly increased during the last 20 years. Meanwhile, cesarean rates for dystocia have increased fourfold to eightfold during that time period. The review of historic information suggests the correctness of our conclusion, which is as follows: To reduce the need for cesarean section in nulliparous patients, administer more oxytocin to more patients for longer time periods.

What factors have caused the decrease in dose, duration, and frequency of use of oxytocin during the time period of escalating cesarean rates for nonprogressive labor? Haverkamp et al.[24] found an increase in cesarean rates for dystocia with the use of intrapar-

tum electronic fetal monitoring as compared with those in patients undergoing auscultation. Seitchik and Rao[23] noted that " . . . the increased use of cesarean sections for the treatment of dystocia in the past decade was associated with the use of electronic monitoring of uterine activity." They further noted that therapeutic goals for oxytocin-augmented uterine activity have been recommended but have no experimental basis. Eighteen percent of their patients in normal spontaneous labor, who experienced spontaneous vaginal delivery, averaged more than 250 Montevideo units (MU). In contrast, the currently used definition of adequate labor by the American College of Obstetricians and Gynecologists[25] includes labor patterns generating as little as 200 MU. In the search for reasons behind the escalating cesarean rates for dystocia, Seitchik and Rao[23] asked, "Is it possible that the premonitor clinician at the bedside, who used palpation for evaluation, achieved greater uterine activity with oxytocin in those patients than we are now obtaining with the electronic monitor as our guide?"

In more recent reports Seitchik et al.[26] advocated the low-dose schedule mainly on the basis of their observations regarding the oxytocin treatment of functional dystocia and the time required for individual doses to cause a steady state in the plasma. In their study population they noted a maximum mean dose of oxytocin of 6.9 ± 5.9 and 4.1 ± 3.8 mU (mean ± 1 SD) for cesarean and vaginal delivery patients, respectively; they concluded that failure to achieve vaginal birth was due to disabilities of the patient and not differences in the application of management principles. We disagree, believing that patients experiencing functional dystocia differ in the amount of uterine activity required to achieve vaginal birth just as do women who are in spontaneous normal labor. Therefore the effective oxytocin doses required by some patients with dysfunctional labor are expected to be much higher than those used in the study of Seitchik et al. We see no evidence that higher doses would not have resulted in the need for fewer cesarean sections. The reports of O'Driscoll et al.,[5] the historic relationship between oxytocin doses and cesarean rates, and the data in this report all support that contention. A randomized, controlled trial comparing low- and high-dose oxytocin schedules with successful vaginal delivery as the end point is needed to provide proof of this contention. The low cesarean rate physician group used a much higher maximum mean dose of oxytocin than the high cesarean rate physician group (18.3 vs 11.9 mU). Neonatal outcomes were no different. The doses used by the low cesarean rate physicians are more than double those of Seitchik et al.[26] (6.9 and 4.1 mU for cesarean and vaginal births, respectively, in their oxytocin-treated patients with functional dystocia).

A further reason for the use of an insufficient dosage of oxytocin has been the perception of increased risk to the fetus associated with its use. We believe that the risks to the fetus of traditional oxytocin dose regimens have been exaggerated and perpetuated without a scientific basis, in spite of its safety regarding both newborn and long-term morbidity. One of the concerns emanates from the belief that traditional or high-dose oxytocin may cause excessive uterine activity resulting in decreased uteroplacental blood flow and fetal hypoxia. Reassuringly, Thorp et al.[27] demonstrated similar umbilical cord blood gas values from those newborns whose mothers received high-dose oxytocin augmentation and those who received no oxytocin. Additionally, oxytocin has often been cited as a cause for "brain damage" particularly in litigation cases, in spite of the work of Nelson and Ellenberg[28] demonstrating no overrepresentation of cerebral palsy in association with oxytocin use in labor (0.3%). These collaborative perinatal project data come from deliveries occurring between 1959 and 1966 when the traditional high doses of oxytocin were in vogue. The low-dose schedule currently recommended by The American College of Obstetricians and Gynecologists[25] and the *Physicians' Desk Reference* is an additional deterrent to the use of appropriate oxytocin doses, particularly in view of legal risks.

Do "modern" (low) oxytocin dose regimens generate "modern" (high) cesarean delivery rates? Probably. We conclude that a cesarean rate reduction program for patients with dystocia will be successful if it includes more oxytocin for more patients for longer periods of time and if physicians wait until more advanced cervical dilatation is achieved before administration of oxytocin.

Discussion

DR. DWIGHT P. CRUIKSHANK, Milwaukee, Wisconsin. Drs. DeMott and Sandmire have presented data that suggest that a significant reduction in the primary cesarean rate can be accomplished by the "three mores"—*more* oxytocin to *more* patients for *more* hours. They confirm the clinical impression that many of us have, that the recent trend regarding oxytocin usage is one of the obvious causes of the increased cesarean rate. They rightly point out that medicolegal concerns probably inhibit oxytocin use, particularly in view of the low-dose schedule currently recommended by the *Physicians' Desk Reference.* Therefore let us examine what the PDR says about oxytocin and why.

In the section regarding Syntocinon oxytocin injection USP (Sandoz) the 1991 PDR (pp. 1969-70) states, "The initial dose should be no more than 1-2 mU/minute. The dose may be gradually increased in increments of no more than 1-2 mU/minute until a contraction pattern has been established which is similar to normal labor." No references are given for these statements. The section describing Pitocin oxytocin injection USP (Parke-Davis) in the 1991 PDR (pp. 1687-9) is even more restrictive, stating "The initial dose should be 0.5-1.0 mU/minute. At 30-60 minute intervals the dose should be gradually increased in increments of 1-2 mU/minute until the desired contraction pattern has been established. Rates exceeding 9-10 mU/minute are rarely required at term." Five references are given for these statements, including three articles by Dr. Joseph Seitchik and colleagues and the 1987 *ACOG Technical Bulletin* No. 110. That bulletin lists four references regarding oxytocin, including the three by Seitchik. It appears that the work of Seitchik et al. provides the scientific basis for the current low-dose oxytocin protocols, we should examine their findings in some detail.

Between 1982 and 1984, Seitchik et al. published four articles in the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY entitled, "Oxytocin augmentation of dysfunctional labor (Parts I, II, III, and IV)."[1-4] In these studies they reported that dysfunctional labor in nulliparous women could be effectively treated with initial doses of oxytocin of 1.0 mU/min, increased by 1.0

mU/min at ≥30-minute intervals to a dose of 4.0 mU/min, and then increased by 1.0 mU/min every hour at doses above 4.0 mU/min. They found that doses higher than 6 to 7 mU/min were rarely necessary. They also demonstrated, using this low-dose protocol, that approximately 40 minutes was required for any given dose of oxytocin to reach steady-state plasma levels and a maximal uterine contractile response and that oxytocin infusion rates of 6 mU/min produced plasma oxytocin levels comparable to those found in normal laboring women.

I believe there are three major problems with these data, the most important of which is patient selection. All patients were nulliparous and at term and were eventually delivered vaginally. Patients who eventually were delivered by cesarean section for dystocia were not studied, but the articles imply that they too received low-dose oxytocin. The problem is that those patients may very well represent a subset of women who require much more oxytocin to achieve uterine activity. Similarly, although 6 mU/min produced plasma oxytocin levels comparable to those found in normal laboring women, patients with dystocia are by definition not normal laboring women. Whether because of qualitative or quantitative differences in oxytocin receptors or for other biologic differences, these patients may need more oxytocin. Finally, although low doses of oxytocin may take 40 minutes to achieve steady-state plasma levels, it is likely that higher doses would do so much more quickly. Whereas this was not studied with regard to oxytocin, it is certainly true of magnesium sulfate and several antibiotics.

There is a growing body of data, from both Europe and North America, that high-dose oxytocin as practiced in the active management of labor protocol[5] (initial dose 6.0 mU/min, increased by 6.0 mU/min every 15 minutes to a maximum of 40 mU/min) can result in very low rates of cesarean delivery for dystocia, because, as O'Driscoll et al. said, "The problem of dystocia has been virtually solved . . . ."[5] Thorp et al.[6] have demonstrated the safety of such an approach for the fetus and neonate.

In fairness to The American College of Obstetricians and Gynecologists, there is a new *ACOG Technical Bulletin* regarding induction and augmentation of labor (No. 157, July 1991). This bulletin contains the moderate-dose oxytocin regimen of Hauth et al.[7] (initial dose 1 to 2 mU/min, increased by 1 mU/min every 15 minutes), as well as the low-dose protocol of Seitchik et al. and the PDR, and even acknowledges the high-dose active management approach of O'Driscoll et al., while stating that clinical experience with the latter in the United States is limited.

There are several other problems with what the PDR says about oxytocin, namely, that it " . . . should not be administered in the face of prematurity, borderline cephalopelvic disproportion, previous cesarean section, over-distension of the uterus and grand multiparity," among others. I believe there are no reliable data to support any of these, and in fact there are data to the contrary for some. I propose that the American College of Obstetricians and Gynecologists convene a consensus conference of investigators, clinicians, and pharmaceutical company representatives to rewrite the PDR and package insert information for oxytocin to develop more reasonable guidelines for its use, so that physicians will not feel medicolegal risk for using oxytocin in a rational manner.

I have only two criticisms of DeMott and Sandmire's article. First, their three physician groups (low, medium, and high cesarean rates) are artificial. In their low group the cesarean rates for dystocia vary from 2.7% to 5.0%, a spread of 2.3%. In their medium group (range 6.6% to 8.8%) the spread is 2.2%. In the high group, however (range 9.4% to 16.0%), the spread is 6.6%. I suggest that there really are two groups and one outlier. Physicians 1 to 4 are one group with cesarean rates from 2.7% to 5.0%. Physicians 5 to 10 are another group with rates of 6.6% to 10.0%. Then there is physician 11, with a cesarean rate for dystocia of 16%. This physician also had an 0.8% forceps rate, compared with a mean of the rest of the group of 7% (range 3.4% to 14.6%). I suspect that rearranging their groups in this way would not alter the results, except to make them more striking.

My other criticism regards the term *failed labor* in their title. In this litigious age we should not refer to "failed" anything—whether forceps or external version or labor. Elsewhere in their article they use the term *nonprogressive labor*. I would prefer that we stop using these terms, as well as the ubiquitous "failure to progress," and return to the tried-and-true term *dystocia*. I tell medical students that dystocia is the Latin term for the syndrome of WCO—Won't Come Out. However, now we see that most will "come out," if we use *more* oxytocin in *more* patients for *more* hours.

Dr. Richard P. Perkins, Omaha, Nebraska. Drs. DeMott and Sandmire have submitted their extended analysis of operative delivery in Green Bay. After subdividing their practitioners by operative rates, they set about to find differences in practice patterns that would explain these differences in patients not greatly different from each other. In an examination of the data presented, the impression gained by the reader is that the differences discussed are not especially striking, although they appear to satisfy the statistician.

The authors suggest that higher doses of oxytocin given to more patients for longer times will reduce the cesarean section rate. We would suggest that this may be true, but objective analysis of each case is required to determine if, with management by the more aggressive plan, another outcome would be expected. The authors suspected, but did not confirm, that the group with higher rates used lower doses of oxytocin. This was shown for induced labors, but augmentation dose means for the high-rate group fell intermediately between those of the low and medium groups. The same can be said for the high group for cervical starting points, frequency of augmentation, first-stage and second-stage lengths, percent of cesarean patients with complete dilatation, and mean cervical dilatation before cesarean section.

I am not certain that the conclusions are pure without eliminating those babies born by cesarean section who were significantly above the mean in weight and size and then seeing if the difference remained. This should be required if the effect of augmentation is said to be paramount. I am also not certain that the numbers here are great enough to demonstrate the true significance of the differences if they exist.

It is in the best traditions of medicine for each local hospital and group of cooperative physicians to analyze medical practice and modify patterns accordingly. It requires agreement on the reasons for the task and a healthy view toward the goals being those of improved care and outcomes. I applaud this effort by these authors.

I submit that if each physician were required to fill out a questionnaire before performing cesarean section for failure to progress and if these questionnaires were analyzed periodically, a better insight would be achieved and fewer cesarean sections would be done. We are looking at this ourselves. Pertinent questions to be answered would be the following:

1. Has the cervix ever changed?
2. Are contractions adequate? Monitored objectively? Frequent and strong?
3. Is the cervix at least 4 cm dilated?
4. Is there molding of the presenting part?
5. Is the presenting part in the pelvis?
6. Is the bladder empty?
7. Has progress been arrested for at least 2 hours?

Failure to progress is indeed the commonest indication for primary cesarean section, but failure of whom or what to progress is the issue in doubt. Is it the patient or the provider?

Fetal monitors have given us the ability, if not the inclination, to be more patient with slow labor progress. With the declining expertise with midpelvic forceps and the increasing use of epidural analgesia, expected increases in cesarean section have been observed and may well persist in spite of the benevolent redefinition of midforceps recently proposed. The Green Bay study also reminds us that it is far easier to describe behavior than to determine motivation.

There are subtle pressures also. It is not so much fun to await delivery any more because it used to represent a great relief to the patient and the beginning of life. It is now a great relief to the provider and the ending of a slow "death," worrying about the possibility of an unexpectedly bad outcome that is unrelated to anything he did but at risk of being attributed to him.

What we are all looking for in any plan is a set of guidelines that meet the following qualifications: (1) They seem reasonable; (2) they are acceptable to most patients and providers; (3) they are achievable in the patient's circumstances; (4) those who propose them will effectively back us up should we get sued for using them.

The latter represents the greatest crisis of confidence in medicine today, and its lack, more than any other phenomenon, makes reasonable people do unreasonable things sometimes. In time of war, battles are rarely fought by those who plan them. The court seems to function as little more than a graduate level vocational retreat for ex-members of high school debating teams.

In Hawaii and other places there is a little lizard called a gecko, which, under attack, will shed its tail in the hope of fooling or satisfying the enemy while the rest of the creature beats a hasty retreat. The tail, curiously, continues to wriggle enticingly for a time until the creature is safely away. My concern is that in this case the tails of the gecko are current intervention rationales, which have been left behind in an era of intense litigative pressure and which are still twitching. Soon, however, we will have forgotten how these and so many other defensive stratagems spawned during this age of judicial theatrics came to be, and the "standard of care" will at length have been established mindlessly even after the disturbed rationale has been forgotten. This leaves us with the empty feeling that American obstetrics, while ostensibly in pursuit of a body of knowledge, may achieve nothing more significant than chasing part of a tail.

Finally, the authors consistently capitalized *cesarean,* as if it were named after someone. As we know, the word comes from the Latin word meaning "to cut." We come to bury the cesarean section, not to praise it. Perhaps we need another term—the "unnecesarean section rate."

Dr. Charles W. Schauberger, La Crosse, Wisconsin. Someone suggested that Friedman's curve is a use-

ful tool for the management of labor. Others suggest it is used too frequently to justify performing a cesarean section too early. How frequently is Friedman's curve used at your hospital and are there differences within the three study groups?

Dr. Richard A. Hartman, St. Louis, Missouri. We have an institution in St. Louis, Barnes Hospital, at which one physician amassed about 4000 deliveries during which the patients received epidural analgesia, and the question I'm going to ask is about epidurals. That physician has been able to show that if an epidural anesthetic is given at a cervical dilatation of <3 cesarean section rates of >35% result. If the epidural anesthetic is given between 3 and 5 cm of cervical dilatation, the cesarean rate is somewhere between 11% and 35%. If dilatation is >5 cm, the cesarean section rate is about 11%.

We have institutions in St. Louis where the cesarean section rate ranges from 10% to 35%, not just for physicians but for the institutions. There are a lot of people who feel that the epidural analgesic altered the cesarean section rate. Ten years ago 15% of women received epidural anesthetic. Now almost 90% do so. I just wonder what effect this would have on the data.

Dr. James R. Scott, Salt Lake City, Utah. I just wanted to raise the issue of what are adequate contractions and how they were defined in this study. Was there a difference in how physicians actually decided to use oxytocin when there was failure to progress?

Dr. Elliot M. Levine, Chicago, Illinois. I'm wondering if the authors mentioned the fear of a lawsuit as perhaps being a stimulant for cesarean delivery. I'm wondering if, in fact, the authors did look into the litigation history of the obstetricians mentioned in this study.

Dr. William E. Houck, St. Louis, Missouri. I just have a follow-up comment on several other statements about invasive contraction monitoring. Was there any difference between the use of this in the high-risk versus the low-risk groups?

And one other issue—you mentioned the timing of delivery. Was there an increased incidence of deliveries about 5 PM?

Dr. James D. Funnell, Oklahoma City, Oklahoma. I would like to raise a different set of issues that has to deal with those of us involved in a training program. In training programs throughout the United States there is great variation in the use of oxytocics and the teaching of forceps deliveries. While these vary from institution to institution, they must be factored in when studies such as this are reviewed.

Dr. John W. Calkins, Kansas City, Kansas. As a kind of correlate to Dr. Funnell's statement, I found interesting the differences in the number of operative vaginal deliveries among the different obstetricians. I wondered if the authors looked at the number of years in practice (or the experience of the physicians) to see if that correlated with this specific factor because clearly our residents don't get the experience that residents did 10 years ago in forceps deliveries.

Dr. Sandmire (Closing). Dr. Perkins mentioned that, concerning some of these practice patterns that we measured, there really wasn't much difference between the high and medium cesarean rate physician groups. I agree with that but would point out the substantial differences in comparing the low group to the high group or the combined high and medium groups. We still believe that the results and conclusions are valid but also agree with Dr. Cruikshank's suggestion that there should be only two physician groups and one outlier.

Dr. Cruikshank expanded on our concerns relative to inadequate oxytocin doses and spurious contraindications to its use. Appropriate usage of oxytocin depends on proper patient selection, as well as adequate dose levels. The patient with false labor or the patient with an unripe cervix who has insufficient indications for labor induction should not receive oxytocin. On the other hand, virtually all patients with vertex presentations who are experiencing nonprogressive labor should receive adequate doses of oxytocin before the physician resorts to cesarean section.[1] We agree completely with Dr. Cruikshank's recommendation for a consensus conference to develop more reasonable guidelines for its use. Our concerns have previously been forwarded to The American College of Obstetricians and Gynecologists.

We agree with Dr. Perkins that defensive medicine decision making, which we all practice to various degrees, is not a satisfactory response for a scientific discipline. In addition, it usually is not effective. As Dr. Mortimer Rosen has said, "If you have a bad outcome, you're going to be sued. If you have a good outcome, you're not going to be sued. So if you have a bad outcome, you're going to get sued anyway. You might as well have the satisfaction of practicing good medicine."[2] Furthermore, even by practicing defensive medicine, you're not going to avoid the lawsuit. This emanates from the creativity of the experts who will be able to testify that some management decision you made was questionable. This will be presented to the insurance company and the insurance company will settle the case if the demand is low enough. In Wisconsin we have "frequent flyers" from both coasts who come in and testify against Wisconsin obstetricians, and they have a level of creativity that is very high. I hate to paint a bleak picture, but I think Dr. Rosen is right. We have to guard against the decisions that are based on defensive medicine.

Dr. Schauberger asked about the Friedman curve. We didn't test that. That's something that the individual nurse decides. It's done in most but not all cases.

We generally agree with Dr. Perkins' list of questions to ask ourselves before performing a cesarean section for failure to progress. Perhaps to expand slightly on his assessment of the contractions, we offer our definition of adequate contractions not as how hard the

uterus feels, how frequent the contractions are coming, how long they last, or what the bottom line on the monitor strip demonstrates. We define adequate contractions as those that produce progressive dilatation and/or descent; and if they are not doing that, we do not have adequate contractions. Admittedly, with the presently available interventions, we are unable to achieve adequate contractions in some patients.

Regarding epidural anesthetic—I think that to give a patient something that will interfere with her ability to push and maybe the contraction strength is the last thing that I want to do. We don't use epidural anesthetics in Green Bay. I think that there are many studies, although not randomized, that show that epidural anesthesia increases the cesarean rate.

I answered Dr. Scott on what is the definition of an adequate contraction. Dr. Levine asked about the litigation histories of the 11 obstetricians. As I said 2 years ago, regarding these 11 obstetricians, they all know about the Green Bay lawsuits because some of their partners have been sued, and for the young ones who haven't, I tell them, "Be patient." So they all have equal knowledge of the liability risks.

Vaginal birth after cesarean delivery: Are there useful and valid predictors of success or failure?

Mark G. Pickhardt, MD,[a] James N. Martin, Jr., MD,[a] Edward F. Meydrech, PhD,[b] Pamela G. Blake, RN, MSN,[a] Rick W. Martin, MD,[a] Kenneth G. Perry, Jr., MD,[a] and John C. Morrison, MD[a]

Jackson, Mississippi

OBJECTIVE: Before parturition are there useful and valid predictors of successful or unsuccessful vaginal birth after previous cesarean birth that could be used to enhance the obstetric care of a patient and her pregnancy?

STUDY DESIGN: The clinical course and outcome of all patients who attempted vaginal birth after cesarean delivery at one level III center during 1989 were evaluated to identify factors prognostic of a successful or unsuccessful patient group: use of this information in stepwise logistic regression and cluster analysis was disappointing.

RESULTS: No single criterion or optimal clusters of factors were found and no equation achieved >75% predictability of outcome with acceptable sensitivity and specificity.

CONCLUSIONS: Before parturition prediction of outcome of vaginal birth after cesarean delivery is tenuous regardless of past obstetric history or recent clinical parameters. Thus it seems appropriate to encourage a trial of labor in almost all patients with a prior low-segment uterine incision (transverse or vertical) unless there is a strong physician or patient-derived contraindication to such an undertaking. (AM J OBSTET GYNECOL 1992;166:1811-9.)

Key words: Vaginal birth after cesarean delivery

Since the early 1970s in the United States there has been a trend away from the practice of elective repeat cesarean delivery toward trial of labor in selected patients who have undergone abdominal delivery.[1, 2] Abundant obstetric literature has substantiated the safety and efficacy of this evolution in obstetric care.[3-6] The trend has been aided significantly by the American College of Obstetricians and Gynecologists, which in published guidelines clearly support and encourage the concept of vaginal birth after cesarean delivery.[7]

In spite of knowledge regarding the safety and success rate of vaginal birth after cesarean delivery, a method to reliably predict a successful or unsuccessful attempt before the onset of labor would further enhance clinical care. The present investigation was undertaken to determine if there is an association between specific obstetric variables or combinations of these variables and a successful or unsuccessful trial of labor on an individual basis.

Material and methods

A computer-directed search of the medical records of obstetric patients who delivered at the University of Mississippi Medical Center during the calendar year 1989 was undertaken to identify all women with a previous cesarean delivery who underwent a trial of labor in a subsequent pregnancy. The records of 312 patients were identified for analysis. Twenty-four charts could not be obtained. Thus 93% of all possible patients were available for study, and these subjects were divided into women who experienced a vaginal birth (successful) and those who had an abdominal delivery after a trial of labor (unsuccessful). Nineteen specific obstetric variables or factors (Table I) for each patient were obtained from the clinical courses and outcomes of both successful and unsuccessful attempts at vaginal birth after cesarean delivery.

Cervical assessment (favorability) was performed by recording cervical dilatation, effacement, and station and using this information for a modified Bishop score with a maximum score of 6. The terms recurrent and nonrecurrent indications for previous cesarean delivery are defined as follows: recurrent—failure to progress, cephalopelvic disproportion; nonrecurrent—fetal distress, twins, breech, severe preeclampsia, herpes, or prolapsed umbilical cord.

Appropriate univariate analyses were conducted with t tests or χ^2 analysis. Stepwise logistic regression with probablity of entering the model equal to 0.05 was used

Table I. Factors considered in study of vaginal birth after cesarean delivery study

Variable	*No.*
Race	309
Age	309
Height	254
Weight	299
Gravidity	312
Parity	312
Cervical dilatation in centimeters	309*
Effacement	299*
Station	301*
Modified Bishop score	309*
No. of previous cesarean sections	312*
No. of previous vaginal deliveries	312*
Indication for previous cesarean section	312*
Estimated gestational age	309*
Spontaneous rupture of membranes	312
Placental grade by sonogram	85
Fluid status by sonogram	97
Spontaneous uterine activity	312*
Estimated fetal weight by sonogram	101*

All 19 factors investigated for relationship and prediction validity to successful vaginal birth after cesarean delivery are listed with those identified by asterisks if significance ($p < 0.05$) was observed.

*Significant at $p = 0.05$ level.

Table II. Logistic regression summary

Variable	*Coefficients*	
	Equation 1	*Equation 2*
Constant	−4.4183	−8.6165
Estimated fetal weight by sonogram	0.0010	
No. of previous cesarean sections	0.7719	0.8326
Cervical dilatation in centimeters		−0.4803
Estimated gestational age		0.2160
No. of patients	101	306
Sensitivity (%)	60.4	38.4
Specificity (%)	66.0	87.9
Correct (%)	63.4	71.9

Two different equations with stepwise logistic regression procedure produced different outcomes.

to determine if the number of these variables could be reduced and combined to explain the probability of vaginal birth, p, given by an equation of the form

$$p = 1/(1 + \exp^{-x})$$

where x is a regression equation involving the selected variable and their coefficients. Cluster analysis was performed to detect natural groupings of the independent variables regardless of the dependent variable. The Statistical Analysis System (Statistical Analysis Systems, Inc., Cary, N.C.) was used for all analyses. A significant difference was defined as a p value of ≤ 0.05.

Table III. Cumulative frequency distribution of p values derived from either two equations with associated predictive values

	Equation 1		*Equation 2*	
	Vaginal	*Cesarean*	*Vaginal*	*Cesarean*
$p = 0.050$	5.7	0.0	9.7	1.0
$p = 0.100$	11.3	0.0	18.8	1.0
$p = 0.150$	20.8	0.0	30.4	3.0
$p = 0.200$	24.5	0.0	45.4	10.1

$p = 0.950$	100.0	100.0	100.0	99.0
$p = 1.000$	100.0	100.0	100.0	100.0

Results

Among the 4211 pregnant patients delivered of live-born infants at the University of Mississippi Medical Center during 1989, there were 495 women (11.7%) who had prior abdominal delivery. A trial of labor with attempted vaginal delivery was undertaken in 336 patients (67.9%). There were 24 with indeterminant outcomes due to lost charts (7.1%), 212 (63.1%) successful outcomes, and 100 (29.8%) who required repeat abdominal delivery.

Table I lists the 19 factors that were studied and the number of deliveries for which data in each case was available for analysis. Ten factors individually were significantly related to birth outcome ($p < 0.05$). Vaginal birth occurred more often than required repeat cesarean delivery in the presence of spontaneous labor, a favorable cervical vaginal examination at the time of hospital admission, lower ultrasonographically estimated fetal weight (with biparietal diameter and abdominal circumference) and gestational age, and previous vaginal delivery with fewer prior cesarean births, as well as when prior abdominal delivery was associated with nonrecurrent indications (Fig. 1).

Combinations of two or more factors for prediction of outcome was undertaken. Two very different outcomes were found with the stepwise logistic regression procedure. The reason for this difference is that the estimated fetal weight by ultrasonography was measured in only 101 of the subjects, and logistic regression permits subject inclusion only when data for all dependent and independent variables are present for the

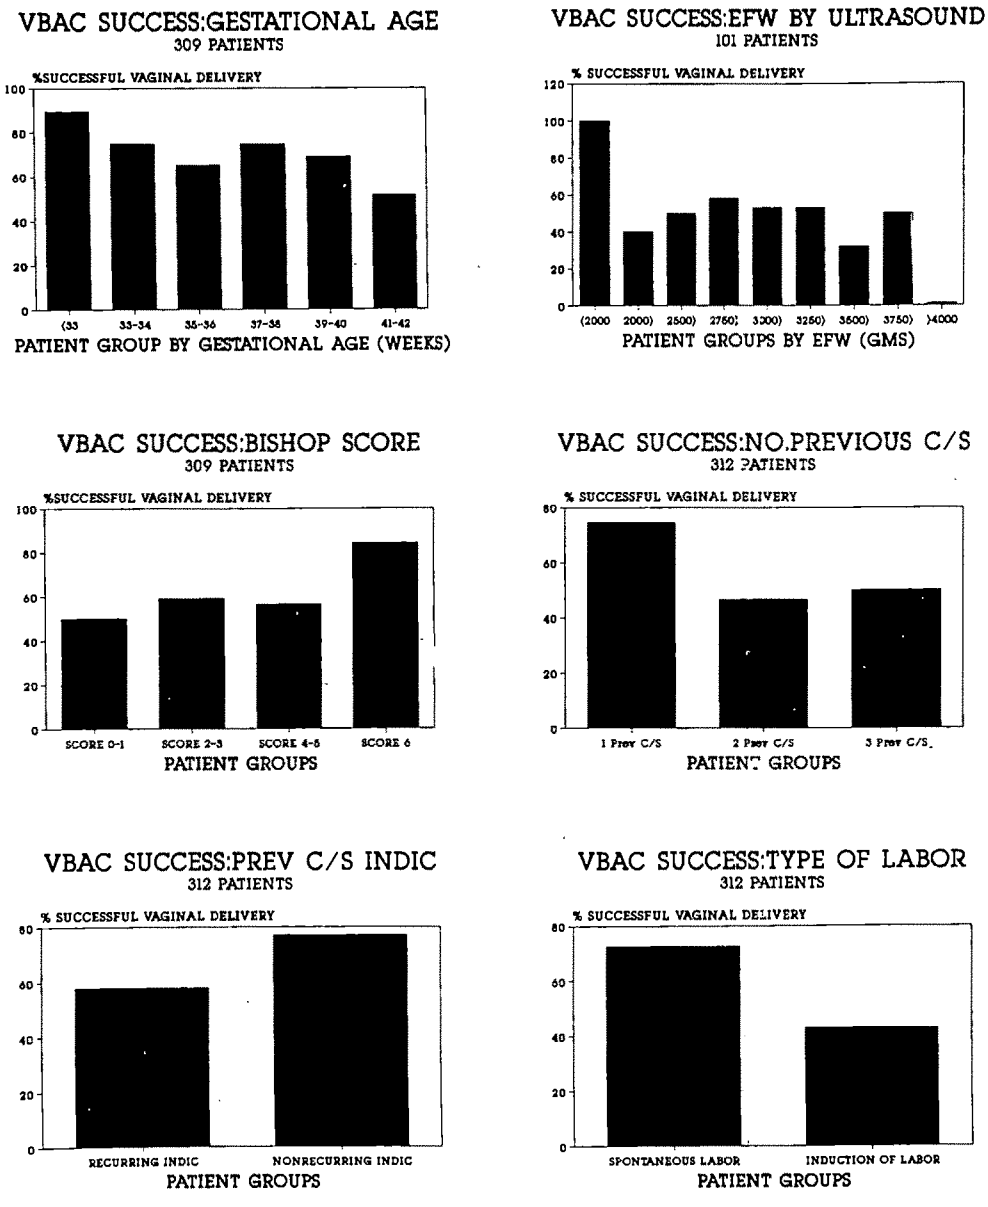

Fig. 1. Six of 10 factors significantly related to birth outcome and vaginal birth after cesarean delivery *(VBAC)* are depicted graphically in this display.

computation of estimates. These two equations are summarized in Table II.

In the first equation which includes the estimated fetal weight, it is apparent that the sensitivity (the probability of correctly predicting a cesarean birth, $p > 0.500$) is 60.4% and the specificity (the probability of correctly predicting a vaginal birth, $p < 0.500$) is 66.0% and that the overall rate of outcome prediction is 63.4%. In the second equation estimated fetal weight was dropped from the list of independent variables. Thus data from 306 of the study subjects were used to compute an estimate that produced an equation that has a lower sensitivity (38.4%), a higher specificity (87.9%), and a better rate of overall prediction (71.9%) than the first equation.

Further comparison of the two equations can be expressed by the respective values of R^2, which is the proportion of log likelihood explained by the equation. For equations 1 and 2 these are 0.1018 and 0.1552, respectively, indicating that equation 2 is slightly better than equation 1. However, neither of these figures indicates a clearly superior fitting equation.

Cumulative frequency distributions of the p value given in Table III provide a final possible meaningful use of these equations. For equation 1, $p \leq 0.300$ would predict correctly 28.3% of the vaginal births and in-

correctly 4.2% of the cesarean births, and $p \geq 0.700$ would correctly predict 20.8% of the cesarean births and incorrectly predict 3.8% of the vaginal births. This leaves a majority, 67.9% of the vaginal births and 75% of the cesarean births, that give similar values of p for the two very different outcomes. Similar cutoff values of 0.150 and 0.700 for equation 2 leave 68.2% of the vaginal births and 78.8% of the cesarean births giving similar values of p. These gray areas are indicative of the general lack-of-fit of both statistical models.

The lack of good separation in our equations for outcome prediction is confirmed by the results of cluster analysis. On the basis of the patterns of the pseudo F statistic and the cubic clustering criterion, it is concluded that no optimal clusters of clinical criteria (Table I) were found.

Comment

Women with a previous abdominal delivery who attempt a subsequent vaginal delivery have a high chance of success regardless of clinical parameters. Overall success rates at various institutions in the United States range between 50% and 80%.[3, 5-9] At the University of Mississippi Medical Center, the successful rate of vaginal birth after cesarean delivery in 1989 was approximately 63%, almost identical to the 62% rate reported in a collaborative project from this institution and the University of Alabama undertaken in 1981.[10]

A strong relationship between single or clusters of specific obstetric variables and subsequent mode of delivery (vaginal or abdominal) in patients with previous cesarean operations was not observed in this investigation. In contrast, Silver and Gibbs[11] found that previous vaginal delivery, a nonrecurrent indication for prior cesarean delivery, and any cervical dilatation during the first 2 hours of labor augmentation to be significant global predictors of successful trial of labor/vaginal birth after cesarean delivery in a prospective analysis of 98 patients with one previous abdominal delivery.

Whiteside et al.,[12] in a retrospective review of 194 patients, observed that several specific obstetric variables were associated with successful vaginal birth after cesarean delivery. These included a nonrecurrent indication for previous cesarean birth, a previous vaginal delivery, a duration of labor <24 hours before primary cesarean section, a fetal birth weight <4000 gm, and cervical dilatation >4 cm at the time of admission for trial of labor. In these studies[11, 12] each variable was examined independently and cluster analysis was not undertaken.

Recently, Rosen and Dickinson[8] reported a meta-analysis of 29 studies of vaginal birth after cesarean delivery that investigated the association between successful trial of labor and various individual preexisting conditions. With data from 8770 patients these investigators concluded that a trial of labor, regardless of preexisting obstetric variables, is associated with a >50% chance of successful vaginal birth after cesarean delivery. Compatible with the present findings, no cluster analysis from this large body of patients would be expected to render predictive accuracies for success or failure on an individual basis that would approach a clinically useful 80% to 100% range.

The use of a fetal-pelvic index has been investigated to evaluate its efficacy for the prediction of failure of vaginal birth after cesarean delivery.[13] Using the concept of the fetal-pelvic index to compare the fetal head and abdominal circumferences by ultrasonographic mensuration with the respective maternal pelvic inlet and midpelvic circumferences by radiogaphic pelvimetry, Thurnau et al.[13] studied 65 patients admitted for trial of labor on vaginal birth after cesarean delivery. All 13 patients with a positive fetal-pelvic index value failed to progress in labor and a cesarean delivery was required (positive predictability 1.00). In contrast, 47 of the 52 patients with a negative fetal-pelvic index value delivered vaginally (negative predictability 0.90). Of the five with false-negative fetal-pelvic index values, four fetuses persisted in an occipitoposterior presentation and failed to progress in labor. The investigators observed that neither pelvimetry nor ultrasonography alone provided accurate identification of fetal-pelvic disproportion. Although somewhat cumbersome and demanding of special skills, it is possible that use of this clinical approach late in gestation or early in labor might avert long unsuccessful labor trials in those pregnant women destined to fail attempted vaginal birth after cesarean delivery.

The pilot study to our present investigation examined the results from a sample group of only 100 patients (50 patients who had successful and 50 patients who had failed vaginal birth after cesarean delivery) from the larger patient population reported in this study. Strong associations between pairs of specific obstetric variables and outcome (successful or failed vaginal birth after cesarean delivery) were found. The strongest pairing of variables were associated with a >70% successful vaginal birth after cesarean delivery rate or with a <30% successful rate. Patients especially prone to a failed trial of labor were those with a gestational age >40 weeks, a recurrent indication for prior cesarean delivery, an unripe cervix, and initiation of labor by induction (or any paired combination of these variables).

Expansion of the pilot study population to include all patients who attempted a trial of labor during 1989 at University of Mississippi Medical Center was under-

taken to further validate or refute these initial findings. Additionally, it was thought that subsetting of several variables made possible with a larger study group might show even stronger associations with successful or failed vaginal birth after cesarean delivery that would be of clinical value. Unfortunately, the reverse situation occurred.

Regardless of the analytic equation (1 or 2) used, the optimal subset of variables (Table II) produced overall prediction rates of only 63% and 71%, respectively. In our patient population and obstetric practice the success rate of vaginal birth after cesarean delivery is 63%, whereas in the nation at large the success ranges between 50% and 80%. Thus all the statistical methods used in this investigation for individual patients and that of meta-analysis for groups of patients do not provide better methods of prediction than the general overall expected rate of success in our population. Thus there appears at present to be no specific variables or combinations of historic or clinical variables that would allow the clinician to accurately identify and predict a successful or failed vaginal birth after cesarean delivery on an individual basis.

On the basis of well-documented minimal maternal and fetal morbidity associated with a trial of labor as reported by meta-analysis of a large patient experience in 29 investigations, it seems appropriate to encourage a trial of labor *in almost all* patients with prior low-segment incisions (transverse or vertical) regardless of their obstetric history or their recent clinical parameters. Exceptions to this policy would be the infrequent, carefully selected patient deemed to be at too great a risk for trial of labor on the basis of medical and/or obstetric considerations(s).

Discussion

DR. SUZANNE TRUPIN, Chicago, Illinois. Obstetricians encourage vaginal birth after cesarean delivery because this straightforward course of management does more to improve the safety and economics of birth while enhancing the birth experience than any other single intervention. Dr. Pickhardt and his colleagues from Jackson, Mississippi, in their retrospective study analyzed 312 patients, representing 93% of the trial of labor in his institution during 1989. Their hope was to establish criteria that would allow pregnant women to avoid lengthy, unsuccessful labor trials. It is an interesting concept and one that has not been firmly established for any category of parturient—induction, postdates, presumed macrosomic fetus, or diabetic pregnant woman. Although the investigators found no single variable nor any constellation of variables predictive of success, the data indicates categories of pregnant women especially prone to failure by trend analysis. Specific cases included those of gestational age >40 weeks, those with the recurrent indications of cephalopelvic disproportion and failure to progress, those with an unripe cervix as defined by a modified Bishop's score, and those undergoing labor induction. This paper facilitates the health promotion issue of trial of labor as it contributes to the growing body of literature encouraging us to defocus the issue from who should not undergo vaginal birth after cesarean delivery by demonstrating that patients can succeed regardless of past obstetric history or recent clinical parameters.

Medical parameters of safety have progressively broadened indications for vaginal birth after cesarean delivery. This fact, coupled with the support of the American College of Obstetricians and Gynecologists, has allowed for the expansion of this service nationwide. Yet only 37% of patients with previous cesarean births did not have a trial of labor. This is significantly improved over the elective repeat cesarean rates of 98% reported in 1979 and 92% in 1984.[1] However, this rate is far short of the goal of 11% elective repeat caesarean which some have set their sights on.[2] The economic savings of vaginal birth after cesarean delivery and consumer demand are further stimuli to reaching this goal, yet studies indicate that physician bias is still an im-

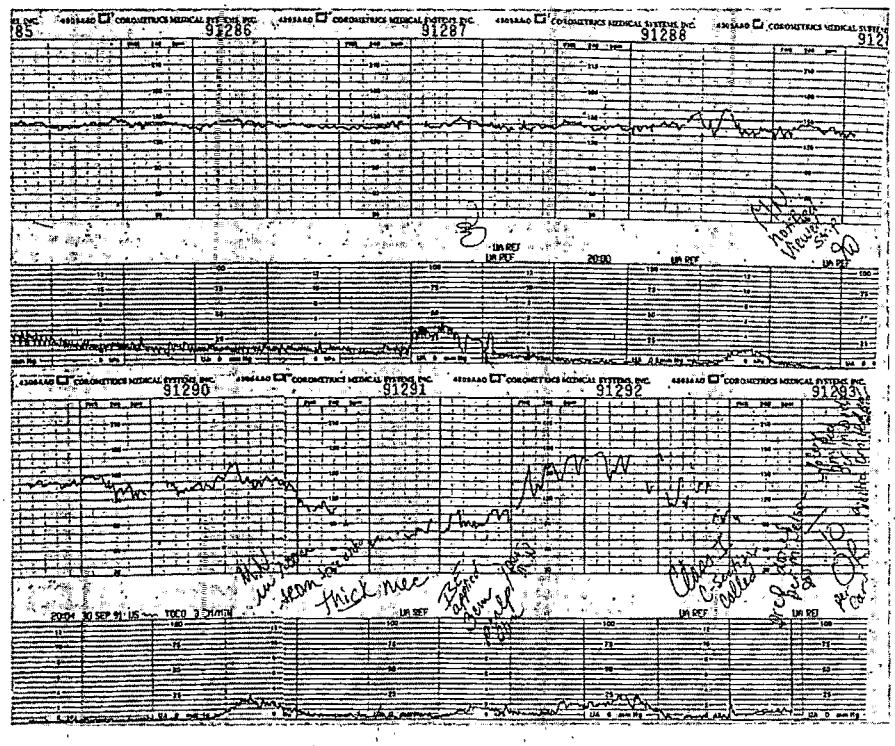

Fig. 1. Uterine tracing of 24-year-old woman, gravida 2, para 1, undergoing trial of labor.

portant influence on individual cesarean birth rates.[3] All of us are influenced by a host of less definable factors such as these two recent cases in my institution: a 24-year-old woman, gravida 2, para 1, undergoing a trial of labor (Fig. 1) or the more frightening 31-year-old woman, gravida 4, para 2, with a previous cesarean section (Fig. 2), both of whom were found to have complete uterine scar dehiscence and massive intra-abdominal bleeding at the time of operative intervention.

My questions regarding this article are (1) What are your criteria for candidacy for vaginal birth after cesarean delivery? Of the 183 patients who did not undergo a trial of labor, what percentage would have been candidates on medical criteria alone? It is possible that because 37% of the population available for study were not studied, the statistics for so-called recurrent indications would indeed be more revealing. (2) Were the authors able to scrutinize the indications for the original and the repeat cesarean birth? Were patients undergoing a trial of labor more quickly assigned the diagnosis of cephalopelvic disproportion than during their first birth? How often was trial of labor abandoned due to the patient withdrawing her consent? (3) Should the labels recurrent and nonrecurrent be discouraged or abandoned? and (4) Because the use of a modified Bishop's score has never been validated, do the authors anticipate that the inclusion of the criteria of cervical position and consistency will enhance predictability?

This article, and the others addressing the issue of successful vaginal birth after cesarean delivery, should further enhance the concept of trial of labor for all. The facts indicate that most patients will succeed. I further propose three ways that we as obstetricians can encourage vaginal birth after cesarean delivery. First, we do not ask our patients, "Are you going to have a vaginal birth?," but rather, "Are you going to have a trial of labor, for if you do you are likely to have a vaginal birth!" Second, we make counseling for trial of labor part of routine prenatal care in spite of the fact that it is not listed as a health promotion objective in the Public Health Service 1989 document on the content of prenatal care.[4] Counseling for vaginal birth after cesarean delivery ideally should begin immediately in the postpartum care of the primary cesarean patient. Third, we do not schedule elective repeat cesarean births. This will discourage us from allowing our convenience to deprive patients of their opportunity to succeed. I look toward the future where elective repeat cesarean birth will be as rare as elective primary cesarean.

1987	14.7/1000	23.0/1000	2 of 4
1988	13.3/1000	23.5/1000	1 of 4
1989	14.9/1000	11.7/1000	None of 2
TOTAL	15.8/1000	24.0/1000	13 of 33

4. Caring for our future: the content of prenatal care. A report of the Public Health Service expert panel on the content of prenatal care. Washington: Public Health Service, Department of Health and Human Services, 1989.

Dr. Leslie Iffy, Newark, New Jersey. The study of Dr. Pickhardt and his associates rests on certain assumptions that to the authors appear self-evident.

The first premise is that the "obstetric literature has substantiated the safety and efficacy" of vaginal birth after cesarean delivery. In support of this conclusion, the writers quote five references. Having experienced no difficulty in identifying another five papers that had found substantial risks involved with the indiscriminate use of vaginal birth after cesarean delivery,[1-5] I am compelled to consider the authors' choices subjective. Of particular interest is the study of Meeham et al.[1] who found a 30.3 per 1000 perinatal mortality rate in association with vaginal birth after cesarean delivery as compared with 22.5 per 1000 in their overall obstetric population and 10.6 per 1000 among patients delivered by repeat cesarean section. Interestingly, the yearly Clinical Reports of the National Maternity Hospital, Dublin,[6] the bastion for vaginal delivery, show that between 1983 and 1989 the perinatal mortality rate in association with vaginal birth after cesarean delivery trials was 50% higher than in the overall institutional population (Table I). A close evaluation of the relevant data reveals that the surplus derived from losses directly attributable to attempted vaginal birth after cesarean delivery.

The second assumption of the authors is that because

of the safety of vaginal birth after cesarean delivery it is "appropriate to encourage trial of labor . . . regardless of past obstetric history or recent clinical parameters." Actually, even those reassuring data that the writers quoted rested on selective use of vaginal birth after cesarean delivery, undertaken after the elimination of risky cases. Thus the relative safety in well-selected cases does not, by any means, permit the conclusion that it is still safe even if the risk factors are ignored.

The third cornerstone for the conclusions of the authors is the assumption that it is a >75% predictability of failure of vaginal birth after cesarean delivery that offers an "acceptable sensitivity and specificity" for an elective cesarean section. For this arbitrary stipulation they offer no explanation. It is understood that the choice between alternative procedures depends on respective risk-benefit ratios. Noting that the maternal infectious morbidity after a cesarean section performed after active labor is about three times as high as after an elective operation,[7] it seems to me that a less than average (i.e., <65% to 70%) chance for vaginal delivery probably serves as a reasonable justification for an elective repeat cesarean section. By its very nature, labor and delivery has an intrinsic fetal risk, as demonstrated by Hellman and Prystowsky[8] decades ago. That this risk still exists is indicated by the earlier quoted data showing that vaginal birth after cesarean delivery carries a higher rate of perinatal mortality than does elective cesarean section. The same conclusion derives from the recently conceded inability of fetal heart rate monitoring to accurately predict neonatal outcome.

In their review of the literature, the authors mention one study[9] that found excellent predictive value for vaginal birth after cesarean delivery failure on the basis of the fetopelvic index. Indeed, the fetopelvic relationship has been shown to be a good predictor for successful vaginal delivery.[10] I find it unfortunate therefore that the authors elected to draw far reaching conclusions about the unpredictability of failed vaginal birth after cesarean delivery without incorporating this parameter of investigation into their study. Their suggestion, namely, that the limited predictability of the outcome warrants indiscriminate use of vaginal birth after cesarean delivery in clinical practice is more likely to discredit this approach in the long run than to promote its use under appropriate circumstances.

Dr. Marvin L Hage, Durham, North Carolina. I would first question the implications of your findings by your exclusion of patients in the study from the analysis. In other words, the exclusions may have biased your interpretation of the significance of the results. Second, what information was provided to the patients? Would their behavior have been altered related to undertaking a trial of labor with these kind of predictive values?

Dr. Martin (Closing). First of all, Dr. Trupin asked why 180 patients did not undergo trial of labor in our study. The criteria to exclude these patients were multiple and varied. We are fairly liberal in Jackson to undertake vaginal birth attempts after prior cesarean operations. We attempt, as you noticed, more than 60% of possible candidates. Even Dr. Bruce Flamm, who is a very great proponent of vaginal birth after cesarean delivery, reported only a 37% or 38% rate of trial labor at his institution. In addition to patients with classic uterine scars or fetal malpresentations, we exclude women who have medical complications of pregnancy that we judge shouldn't warrant an attempt, patients with marginal pelvimetry, and a variety of special situations that are difficult to quantify. The use of medical criteria alone would include complicated hypertension, poorly controlled diabetes mellitus, and so forth. Generally, a patient with a prior low vertical incision is encouraged to undertake a trial of labor.

The issue of a failed trial of labor in association with a failure to progress was raised by Dr. Trupin. We did not do a definitive analysis of why each of the 100 women who underwent unsuccessful trial of labor didn't succeed. The purpose of this investigation was to see if we could develop a type of Bishop score for the individual patient to predict the possibility of successful vaginal birth after cesarean delivery. Our purpose was not to argue the issue of whether trial of labor after cesarean is safe or unsafe as raised by Dr. Iffy.

Dr. Roy Pitkin's comments in a recent *Obstetrics and Gynecology* commentary after an article by Dr. Jim Scott are relevant at this point in that vaginal birth after cesarean delivery has been shown to be safe in capable hands, but this is not a warrant for unlimited use of it without appropriate restraints and care.

Should the terms *recurrent* and *nonrecurrent* be abandoned? I don't know. We use them because they're fairly traditional terms and so that others will understand what we are talking about.

At the University of Mississippi Medical Center we also offer a trial of labor to all patients with acceptable criteria as if it were the expected norm. This is in answer partially to Dr. Hage's questions. A lot of old issues die slowly, and it will take some time to educate physicians and patients to this general policy of widespread trial of labor. As Dr. Jerry Joseph indicated last year, how the physician presents this issue to the patient from the beginning of the next pregnancy has tremendous importance.

In recent years at Mississippi we have educated our resident staff to expect that vaginal birth after cesarean delivery will be undertaken as a rule rather than an exception.

Finally, does favorable cervical condition enhance the predictability of a successful trial of labor? During the first half of this study we evaluated a subset of this patient population. At that early stage we were of the impression that a favorable Bishop score was strongly associated with success or the converse. The data seemed to suggest that if a patient got to 41 to 42 weeks, had an unfavorable cervix, and the fetal vertex was not engaged, that the chance of a successful trial of labor was almost nil.

It turned out that as the numbers expanded to a full population, the association between favorable Bishop score and vaginal delivery was not as strong as anticipated from early data. I suspect that if we could increase this population to a thousand patients, we would see again that our preconceived biases about who will succeed and who won't will fall by the wayside if we consider the individual patient before the onset of labor.

Whiteside's group is the only one that I can recall that has evaluated conduct of labor as a predictor of vaginal delivery. I think this area would be an appropriate place to study next.

Dr. Iffy asked about the risk of vaginal birth after cesarean delivery. As I've indicated, I don't really think that this is an appropriate podium on which to debate that issue. The Dublin information, by the way, did not exclude perinates that had congenital abnormalities and so forth; and of course, their uncorrected perinatal mortality rates were high. When that correction is made, I don't think the risk to the perinate was significantly increased above controls.

Indiscriminate use of vaginal birth after cesarean delivery was addressed earlier.

In closing, we should emphasize again that trial of labor after previous cesarean birth is a procedure that works well. It does require, however, that each of us as responsible clinicians enter into it with caution and that patients are monitored very closely, as we would monitor any patient in labor. Three of the women that had rupture of transverse incisions in Dr. Jim Scott's recent report in *Obstetrics and Gynecology* were not being monitored closely at the time. We need not have that happen. It appears that we cannot predict the success or failure of the individual patient any better than overall chance would suggest.

Comparison of dynamic image and pulsed Doppler ultrasonography for the diagnosis of the small-for-gestational-age fetus

Joseph M. Miller, Jr., MD, and Harvey A. Gabert, MD
New Orleans, Louisiana

OBJECTIVE: Because poor fetal growth is a significant cause of perinatal morbidity and mortality, a prospective study was undertaken to evaluate the ability of real-time ultrasonography and Doppler velocimetry to detect the small-for-gestational-age fetus.
STUDY DESIGN: A prospective study of 136 women at risk for fetal growth abnormalities was conducted. Patients were delivered within 3 weeks and had live-born, nonanomalous, singleton infants. The relative estimated fetal weight (estimated fetal weight divided by the median birth weight for gestational age) and the systolic/diastolic ratio were measured and compared with receiver-operator characteristic curves. In this method the area under the curve is the index of performance.
RESULTS: Forty-six infants were small for gestational age. Although both relative estimated fetal weight (area under the curve = 0.923) and systolic/diastolic ratio (area under the curve = 0.837) were significantly associated with the small for gestational age fetus, the former was more strongly correlated, $p = 0.021$.
CONCLUSION: Relative estimated weight is more sensitive and specific and should be the preferred parameter when gestational age is known. (Am J Obstet Gynecol 1992;166:1820-6.)

Key words: Ultrasonography, Doppler velocimetry, small-for-gestational-age fetus

Management of the small-for-gestational-age (SGA) fetus requires accurate antenatal identification. To date prenatal diagnosis has revolved around a group of ultrasonographic surveillance methods. Traditional biometry, assessing fetal size, and Doppler velocimetry of the umbilical artery have been evaluated. Both methods have a sensitivity of nearly 80%.[1, 2] Previous studies have found velocimetry to have good correlation with neonatal outcome.[1, 3, 4] Standard ultrasonography was more sensitive, but statistical comparison of techniques was not offered.[1, 5]

The intent of this study is to compare dynamic image and pulsed Doppler ultrasonography for the antenatal identification of the SGA fetus. Specifically, the utility of the velocimetric systolic/diastolic ratio of the umbilical artery and estimated fetal weight relative to gestational age were compared with receiver-operator characteristic curves and standard 2 × 2 tables for dichotomous variables. Relative estimated fetal weight was selected for comparison because of higher sensitivity than other standard ultrasonographic parameters.[5, 6]

Material and methods

The study population comprised 136 patients with singleton pregnancies whose infants were born alive within 3 weeks of ultrasonography. Patients were primarily private and were racially mixed. Only women with a known last menstrual period, intact membranes, and confirmatory early physical examination and ultrasonogram were included. All study patients had live-born infants that were not anomalous. The biparietal diameter, abdominal circumference, and femur length were recorded, as previously described.[6] Fetal weight estimation was calculated by the following formula, which is known to fit our patient population[7]:

$$EFW = 10^{1.3598 + 0.051\,AC + 0.1844\,FL - 0.0037\,AC \times FL}$$

where EFW is estimated fetal weight, AC is abdominal circumference, and FL is femur length. Relative weight was then calculated by dividing the estimated fetal weight by the median birth weight for the gestational age at which the study was done, the latter being taken from standard tables for sea level.[8] For identification of an SGA fetus, a relative weight of 0.80 was selected, because the 10th percentile boundary is approximately 80% of the median birth weight.

Fetal umbilical artery velocity waveforms were measured with a pulsed, gated image—directed ultrasonography system. A free-floating portion of the umbilical cord was identified with dynamic image ultrasonography. The Doppler was then initiated, with the gate placed on the umbilical artery. The typical wave-

Table I. Patient demography

	SGA (n = 46)	*Non-SGA (n = 90)*	*Significance*
Menstrual age at delivery (days)	261.2 ± 23.0	274.4 ± 13.1	$p = 0.001$
Menstrual age at study (days)	254.7 ± 23.2	267.4 ± 14.0	$p = 0.001$
Interval between study and delivery (days)	6.5 ± 6.3	7.0 ± 6.0	NS
Birth weight (gm)	1946 ± 653	3372 ± 689	$p = 0.001$

Data expressed as mean ± SD. *NS*, Not significant.

form was identified by aural and visual evaluation.[9] Fetuses were analyzed during nonbreathing periods. Maximal systolic and minimal diastolic velocities were measured. A systolic/diastolic ratio was calculated from three or more representative waveforms and the results averaged. For the purpose of this study, a systolic/diastolic ratio of ≥3.0 was considered abnormal.[1, 9]

Infants were weighed after delivery. An SGA infant was one who weighed <10th percentile for the gestational age at delivery. Weight tables specific for sea level were used.[8]

To evaluate the accuracy of ultrasonographically obtained parameters in the detection of the SGA newborn, we plotted receiver operating characteristic curves (sensitivity versus 1-specificity). The area under the curve for both relative weight and systolic/diastolic ratio and its standard error were calculated by the method of Hanley and McNeil.[10] Differences in the ability to predict SGA between the two methods were determined by comparing the area under the curve for each curve.[11]

Correlation of dichotomous variables was by χ^2 or Fisher's exact test. Group means were compared by Wilcoxon rank sums. Statistical significance was accepted at 0.05.

Results

Of 136 study participants, 46 (33.8%) delivered SGA newborns. Information concerning gestational age and birth weight is presented in Table I. In 88 (64.7%) of patients studied, the interval between study and delivery was ≤7 days. No difference in this interval was evident between the two groups. SGA newborns were smaller and were delivered earlier.

The receiver operating characteristic curves for relative weight and the Doppler-derived systolic/diastolic ratio are presented in Fig. 1. The areas under the curve and their standard error were 0.923 ± 0.028 for relative weight and 0.837 ± 0.040 for the systolic/diastolic ratio. The curve for relative weight was significantly better than for the systolic/diastolic ratio, $Z = 2.04$, $p = 0.021$.

Presentation of selected points along the receiver-operator characteristic curve for relative weight and systolic/diastolic ratio are presented in Tables II and III. Table II presents data when arbitrary boundaries are selected, and Table III illustrates the patient distribution when the point on the curve is selected to be closest to 100% sensitivity and 0% false positive. Both relative weight and systolic/diastolic ratio are strongly associated with SGA, $p < 0.001$. The predictive value of the positive and specificity for relative weight are about 20% greater than those of the systolic/diastolic ratio.

Comment

Significant differences exist between SGA and non-SGA fetuses for relative weight, derived from ultrasonography, and for the systolic/diastolic ratio, derived from umbilical artery velocimetry. Both methods distinguish between the two groups. Evaluation of the receiver operating characteristic curves indicate that relative weight is more predictive. When selected points along each curve are evaluated, improved sensitivity, specificity, and predictive values of the positive and negative are evident for relative weight (Tables II and III) and are consistent with the report of Divon et al.[5] Our observations are drawn from a population in which gestational age was known. In a setting when gestational age is not known with certainty, the Doppler assessment may be of value in identifying the SGA fetus.

A systolic/diastolic value of ≥3.0 was found to correlate well with SGA status of the fetus. When maximal sensitivity and specificity were identified, a value of ≥2.85 was determined. This latter value is reasonable when the mean gestational age of studied patients is considered. The upper limit of the systolic/diastolic ratio is 2.9 at 37 weeks and 2.8 at 38 weeks.[12]

The optimal break point for relative weight was 0.784, slightly lower than expected. This reduction may be attributed to the tendency of weight estimation formulas to overestimate SGA fetuses.[13]

The identified differences are obtained in a setting in which SGA fetuses were studied and delivered nearly 2 weeks earlier. The systolic/diastolic ratio decreases with advancing gestational age.[9] One would expect a higher systolic/diastolic ratio in the earlier delivered SGA fetuses. In spite of this bias, relative weight worked better. This observation strengthens the finding that relative weight is superior to the systolic/diastolic ratio.

The study population was enriched with SGA newborns. If a more normal population was selected (prev-

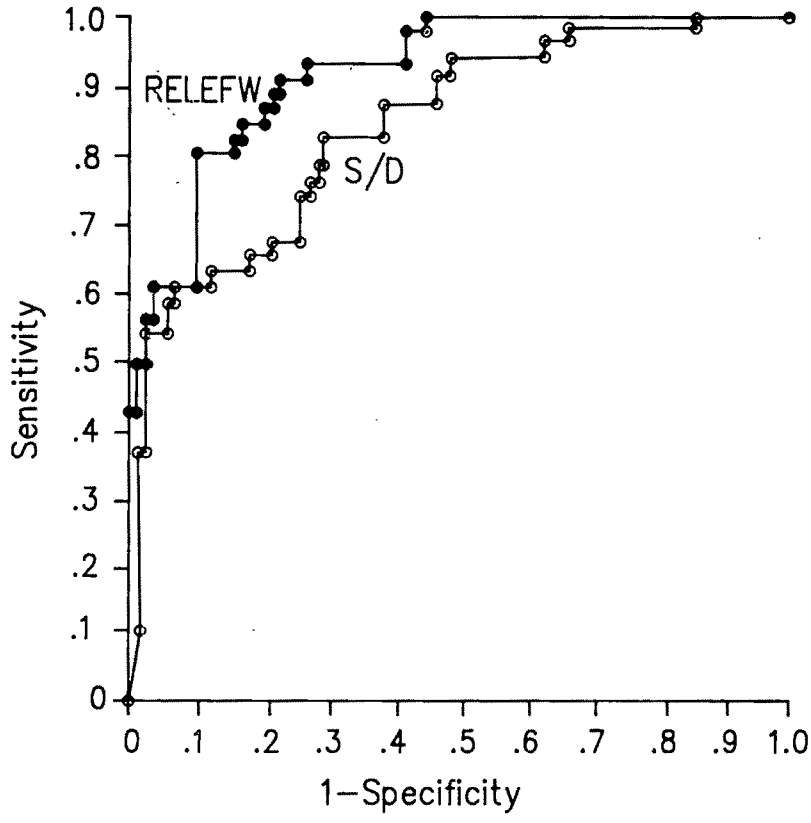

Fig. 1. Receiver-operator characteristic curves of ultrasonographic variables in detection of SGA fetuses. *RELEFW*, Relative estimated fetal weight; *S/D*, systolic/diastolic ratio.

Table II. Contingency tables for ultrasonographic variables versus SGA with a preselected boundary

Variable	*SGA*	*Non-SGA*	*Significance*	*Positive predictive value*	*Negative predictive value*	*Sensitivity*	*Specificity*
Relative estimated fetal weight							
≤0.80	38	13	$p < 0.001$	75%	91%	83%	86%
>0.80	8	77					
Systolic/diastolic ratio							
≥3.0	31	22	$p < 0.001$	59%	82%	67%	76%
<3.0	15	68					

Table III. Contingency tables for ultrasonographic variables versus SGA selected to be closest to upper left-hand corner of receiver-operator characteristic curve

Variable	*SGA*	*Non-SGA*	*Significance*	*Positive predictive value*	*Negative predictive value*	*Sensitivity*	*Specificity*
Relative estimated fetal weight							
≤0.784	37	8	$p < 0.001$	82%	90%	80%	91%
>0.784	9	82					
Systolic/diastolic ratio							
≥2.085	38	25	$p < 0.001$	60%	89%	83%	72%
<2.085	8	65					

alence of SGA 10%) with the boundaries of 0.80 for relative weight and 3.0 for the systolic/diastolic ratio, the predictive value of the positive would decrease to 39.7% and 23.7%, respectively, from application of Bayes' theorem. The predictive value of the negative would increase, 97.9% and 95.4%, respectively; sensitivity and specificity would be unaltered. In a more normal population, both relative weight and the systolic/diastolic ratio would be of value in excluding SGA. In clinical practice, the population specifically studied to detect SGA is often preselected. Therefore assumptions drawn from our data may be appropriate to other settings.

This study addressed SGA newborns as the defined outcome and uses a birth weight–derived definition of SGA. It is reasonable that estimated fetal weight should reflect SGA well. Doppler systolic/diastolic measurements were less useful than standard ultrasonography. The systolic/diastolic ratio may provide insight into the mechanism of diminished growth. Additionally, Doppler measurements may also provide information about fetal health.[14] We concur that their use should be adjunctive.[15]

Clinical management of the SGA fetus is often difficult. We believe that a variety of factors will influence timing of delivery. Serial scans to follow growth of the fetus and some form of antepartal fetal testing for well-being are appropriate. A fetus who fails to grow on serial scans or has an abnormal evaluation of well-being is probably best delivered.

Discussion

DR. EMANUEL P. GAZIANO, Minneapolis, Minnesota. The article supports the generally recognized concept that umbilical artery Doppler measurements offer no significant advantage over standard ultrasonographic biometry for the diagnosis of the SGA fetus. This discussion will focus on three points: the heterogeneity for any given SGA population, methodologic issues, and clinical implications for the findings presented.

Studies relating to the prenatal diagnosis of the SGA fetus by dissimilar methods need to consider, among other things, cytogenetic, infectious, nutritional, and vascular causes. For example, the fetus shown to be SGA on the basis of cytomegalovirus may not necessarily have increased resistance in the umbilical circulation, a prerequisite for abnormal Doppler velocimetry. Although the preponderance of infants in any given population are SGA on the basis of compromised uteroplacental blood flow, did the authors seek to classify the SGA infants on the basis of cause independent of gross anomalies?[1]

The arbitrary cutoff of 3.0 used as a threshold for abnormality is a concern for two reasons. This value was described for studies conducted with continuous wave rather than pulsed Doppler and it does not consider the critical relationship between gestational age and Doppler values. Depending on sample volume size, Doppler indices obtained with pulsed technique as opposed to continuous wave tend to be higher in the umbilical artery for any given gestational age. In our own population, with pulsed Doppler and a sample volume size of 1.5 mm,[2] all patients with a gestational age ≥29 weeks have mean Doppler systolic/diastolic ratios of ≤2.9, which is in close agreement with those reported by Gerson et al. for pulsed Doppler.[2,3] If one considered ≥2 SDs above the mean as the threshold for abnormality, as is suggested by most investigators, a number of patients would be misclassified by the current

study.[1,3] Accuracy could be improved by the construction of a standard curve from the authors' own population and equipment, with the above criteria for abnormality or by use of published normal values for pulsed Doppler, which are adjusted for gestational age.[3] The authors are to be commended for selecting a formulation for ultrasonographic estimation of fetal weight, which includes femur length and for selecting receiver-operator characteristic curves as the statistical method for displaying data, allowing optimal values to be set for test sensitivity.

Table I needs to be expressed in weeks instead of days for time of study and time of delivery.

The study population is surprisingly advanced in gestational age with a mean of 36.4 ± 3.3 and 38.2 ± 2.0 weeks for SGA and non-SGA infants, respectively. The whole construct of the receiver-operator characteristic curves are based on this population. This point needs to be stressed in the discussion because the selected cutoffs would presumably have little or no validity for the diagnosis of the SGA fetus at ≤33 weeks.

The findings that Doppler velocimetry offers no advantage over ultrasonographic estimation of fetal weight is not surprising because one method measures a physiologic parameter, distal resistance to flow, in a heterogeneous population. In addition, ultrasonographic estimations for weight may be more sensitive for the smaller fetus.[4] Does this leave any role for fetal Doppler or will Doppler be consigned as the estriol test of the 1990s? Emerging clinical studies, supported by the present article, suggest the following: (1) that abnormal velocimetry is highly statistically associated with the birth of an SGA infant, (2) that ultrasonography biometry compared with umbilical artery Doppler is superior for the diagnosis of the SGA fetus, and (3) that abnormal velocimetry correlates best with neonatal morbidity and mortality.

A number of studies, including our own work in multiple gestations, support the latter, suggesting that abnormal Doppler velocimetry, particularly in the presence of lower diastolic velocities, demonstrates a strong association with adverse neonatal outcome.[2]

Abnormal velocimetry of the umbilical artery in the presence of ultrasonography retardation of fetal growth warrants close fetal surveillance. Multiple vessel interrogation may help with the timing of delivery, whereas the presence of oligohydramnios and coexisting maternal hypertension remain important clinical variables. Therefore, in the presence of a growth-retarded fetus, Doppler velocimetry may serve as a useful management tool and will likely complement rather than replace standard ultrasonographic biometry.

Dr. Dev Maulik, Kansas City, Missouri. This article investigates the comparative efficacy of ultrasonographic estimation of fetal weight and umbilical arterial systolic/diastolic ratio for predicting birth weights <10th percentile. The former technique has been in use for many years, whereas the efficacy of the latter has been extensively investigated in recent years. The use of umbilical arterial Doppler velocimetry for identifying intrauterine growth retardation (IUGR) is based on the rationale that such a complication is associated with and may be the result of a compromised fetoplacental circulation. This was supported by the important observation that a substantial fall in the umbilical blood flow and subsequent fetal growth retardation can be produced by microsphere embolization of the uteroplacental circulation in a ewe model.[1] Early clinical studies indicated a strong association between abnormal umbilical arterial Doppler indexes and suboptimal fetal growth. This led to optimism about the potential of Doppler velocimetry as a powerful diagnostic tool for fetal growth retardation. Subsequent experience, however, has been mixed at best and often not very encouraging. Some of these contradictory findings may be explained by the semantic and conceptual complexities surrounding the terms IUGR and SGA. Indeed, it should be recognized that not all growth-retarded fetuses are SGA, just at not all SGA infants are growth retarded. Furthermore, it is apparent that not all IUGR or SGA fetuses may suffer from in-utero compromise in terms of asphyxia, which correlates better with absent end-diastolic velocity in the umbilical artery than with subnormal fetal abdominal circumference (<5th percentile), as measured by ultrasonography.[2]

In regard to the various ultrasonographic modalities for recognizing an SGA infant, the majority of the studies have demonstrated that conventional fetal ultrasonographic biometry is more sensitive than umbilical arterial Doppler velocimetry (Table I).

Drs. Miller and Gabert's observations are consistent with these findings. However, their investigation has addressed this issue in a more comprehensive manner by using receiver-operator characteristic analysis for the comparison of the two diagnostic modalities. We have expressed our own preference for this analytic approach in this forum in the past.[7,8] Unlike methods based on the distribution-derived threshold value of a test, the receiver-operator characteristic analysis evaluates overall performance of a test in discriminating between the diseased and the healthy population. The area under the receiver-operator characteristic curve offers a general index of accuracy independent of such factors as population attributes, prevalence rate, or the intended use of the test. A comparison of areas under the relative-operator characteristic curves permits a more logical inferential process.

Table I. Comparative efficacy of ultrasonographic biometry and Doppler velocimetry in detecting SGA infants

Series	*Sensitivity (%)*	*Specificity (%)*	*Positive predictive value (%)*	*Negative predictive value (%)*
Divon et al.[3] (1988)	49/87	94/87	81/78	77/92
Berkowitz et al.[4] (1988)	45/79	89/85	58/64	—
Chambers et al.[5] (1989)	47/73	—	77/84	52/67
Gaziano et al.[6] (1990)	79/43	66/98	21/77	96/93
Miller and Gabert	67/83	76/86	59/75	82/91

In conclusion, I congratulate Dr. Miller and Dr. Gabert for their well-conducted study. However, I believe that several points of clarification are in order. First, it is apparent from the high incidence of SGA infants that the study population was at an increased risk. What were the criteria for selecting the patients in this study, and what were the characteristics of the study population regarding pregnancy complications? Second, a critical element in any study of this nature is an accurate estimation of the gestational age. Although it is mentioned in the article about confirmatory early physical examination and ultrasonography, what were the precise criteria? Finally, an earlier study observed that fetal growth compromise may be detected earlier by Doppler velocimetry than by ultrasonographic biometry.[4] Was this phenomenon noted in this investigation?

DR. CHIN-CHU LIN, Chicago, Illinois. I agree with Dr. Gaziano's opinion that the Doppler study probably looked for the functional rather than anatomic diagnosis of IUGR fetuses by conventional ultrasonographic studies. So it's a different parameter.

From previous literature, it has been suggested that Doppler study for predicting the outcome of the IUGR fetus is not better than various antenatal fetal testings. That includes nonstress testing, biophysical profile, and other testing parameters. My questions are, have the authors compared this Doppler study with those fetal testing parameters? Is this Doppler study better correlated with the diagnosis of IUGR than other antenatal fetal testing methods?

DR. JOE BRUNER, Nashville, Tennessee. From a common sense point of view, simple identification of the SGA fetus is of little interest. Most textbooks point out that 40% of small infants are simply genetically determined to be small. Just like there are big people and little people, there are small infants who are otherwise normal. They're of little interest.

Furthermore, 10% of small infants have severe chromosomal or congenital disorders, and their management is challenging only to a select few. Another 10% are small because of early perinatal infections, and there's little that we can do after the fact to improve outcome in this group.

However, 40% of small babies are small as a result of uteroplacental insufficiency. This is the group we should be most interested in. This group could be identified by a combination of both standard ultrasonographic biometry and Doppler ultrasonography. We should be interested in this group because, in spite of electronic fetal monitoring and biophysical profiles, many of these babies are still born with severe neonatal complications.

So identification of the subgroup of small babies *with* uteroplacental insufficiency should be the starting point for studies trying to decide how best to manage these pregnancies.

DR. DANIEL RIGHTMIRE, Springfield, Illinois. I would like to ask the question that the other two persons from the floor just referred to but didn't ask, and that is, were there different morbidities actually identified among the groups declared abnormal by the two techniques, differences besides smallness? For example, were there differences in the duration of newborn intensive care unit stay or the need for respiratory care or operative deliveries for fetal distress?

DR. MILLER (Closing). Our study population was defined to avoid certain types of complications including cytogenetic or chromosomal abnormalities.

The cutoff point of 3.0 for Doppler studies is prob-

lematic. Our patient population was nearly at term. We chose 3.0 as an arbitrary cutoff; and whether it is right or wrong, it is widely replicated in the literature.

I do agree that Doppler values should be adjusted to gestational age. We chose not to do that since in our community the values are reported as an absolute value compared in that manner.

I concur on the comments with the systolic/diastolic boundaries and their role as gestational age.

Dr. Maulik pointed out the difference between IUGR and SGA, and I could not concur more wholeheartedly. We defined the population as being SGA because that was a relatively easy patient population to define. The problem with defining an IUGR is that I'm not aware of a single widely accepted definition that I could then use to study prospectively. I beg for cooperation from those in the audience to provide such a definition, and we will be happy to use it.

The characteristics of our study population were not presented. We run a consulting service and deal almost entirely with patients who are referred for evaluation and then returned to the practicing physician. The population was indeed rich in SGA newborns, which is not surprising because we were looking specifically to study them. To be sure, chronic hypertension, preeclampsia, poor weight gain, smoking, and other underlying medical complications such as renal disease and lupus erythematosus were among these. These were not recorded.

By early physical examination we meant first-trimester examinations. The patients were all referred by practicing physicians, and patients had been enrolled in prenatal care early. Ultrasonography was generally obtained first, in the first trimester, and if not then, by 16 weeks so that we could define the gestational age. We recognize that there will be minor variations within this. It's unavoidable because we don't have documented ovulation for these patients.

I cannot comment on early growth changes and the ability to determine SGA babies at 24, 28, or 32 weeks because that was not the intent of this study. We do have such data and ultimately will be able to pull them out.

There were some concerns about the functional versus anatomic changes that are being reported. We did not compare these because that was not in our study design, biophysical profile to Doppler. This would be a very interesting study.

I concur that it would be a mistake to walk away from this study believing that Doppler is not of use. Clearly it has a role. I'm waiting for its full role to be defined.

In our study population, however, there was a difference between the two areas under the curve, even though both were excellent, 84% and 92% being reported. The difference in areas under the curve was statistically significant, and that is an important finding from our study. We did not find "no difference." We found specifically that if you want to identify a small baby ultrasonography does so better than Doppler.

Dr. Bruner asked about better identification and the role of Doppler in the IUGR baby. My comments from before will stand.

One would be concerned about the heterogeneous population that we reported. Indeed, my own thoughts are there are several categories of small babies. I see many small babies who weigh 5 pounds to 5 pounds 12 ounces at term and who have grown at a very normal rate over the third trimester. They generally have good amniotic fluid and biophysical assessment, either nonstress test or biophysical profile. These patients are generally delivering smaller but otherwise entirely normal babies.

These are quite different from babies who have a dysfunctional growth process with decreased amniotic fluid, abnormal biophysical profiles, or other abnormal antepartum results.

I would ask that others join us in our efforts to try to differentiate among these entities and to develop a protocol to better focus on both diminished and abnormally diminished growth.

Prediction of respiratory distress syndrome by a new colorimetric assay

Rami Almog, PhD,[a] John W. Goldkrand, MD,[b] Regina A. Saulsbery, BS,[a] and Carol Samsonoff, MS[a]

Albany, New York, and Savannah, Georgia

OBJECTIVE: The purpose of this study was to evaluate the clinical performance of a new, simple, and rapid colorimetric assay for predicting respiratory distress syndrome.

STUDY DESIGN: Ninety-four specimens obtained within 3 days of delivery were assayed with the new test. For 78 of these specimens, the lecithin/sphingomyelin ratio was also determined. Significant differences were calculated with χ^2 analysis. Cutoff points were selected by maximizing the corresponding sums of sensitivity and specificity and from receiver-operator-characteristic curves.

RESULTS: The specificity of the new colorimetric test was better than 89%, and it yielded more than 86% correct diagnoses. Furthermore, the test had a significantly ($p < 0.05$) lower percentage of false-immature results than that obtained with the lecithin/sphingomyelin ratio. Moreover, the new test performed relatively well in analyses of patients between 27 weeks and 36 weeks' gestation.

CONCLUSION: We concluded that the new assay is reliable and that it can serve as a useful alternative to current methods for predicting respiratory distress syndrome (Am J Obstet Gynecol 1992;166:1827-34.)

Key words: Fetal lung maturity, respiratory distress syndrome, colorimetric test for fetal lung maturity

Respiratory distress syndrome (RDS) is still the leading cause of morbidity and mortality among premature newborns.[1] Most methods for predicting RDS are based on the well-known relationship between specific phospholipids in amniotic fluid and progress in fetal lung maturity.[2] The most commonly used clinical test, the lecithin/sphingomyelin (L/S) ratio,[2,3] is labor intensive, time consuming, and generally performed by a clinical technician with special training. Two anionic phospholipids, phosphatidylinositol and phosphatidylglycerol, were suggested by Kulovich and Gluck[4] as additional indexes for fetal lung maturity. An advantage of using these phospholipids is that their low levels in blood should improve the analysis of blood-contaminated amniotic fluid specimens. Phosphatidylglycerol is determined generally by a complex, two-dimensional, thin-layer chromatography procedure[2] or by an immunoagglutination test.[5] This phospholipid is usually detected late in gestation; its estimation is used therefore as a screening test.[2,6] The determination of a phospholipid profile in amniotic fluid may increase the clinical performance over that of the L/S ratio,[2,4] but the procedure is much more labor intensive.

We recently reported on a simple and rapid colorimetric assay for simultaneous determination of lecithin, phosphatidylinositol, and phosphatidylglycerol in amniotic fluid.[7] The assay is based on the capabilities of these phospholipids to solubilize a solid dye complex adsorbed on glass beads. We simplified the original procedure and made it more convenient for clinical use. In this communication we describe the improved assay and report on a clinical evaluation of the new test in assessing fetal lung status.

Material and methods

Phospholipids for calibration curves were purchased from Sigma Chemical Company (St. Louis). Amniotic fluids were obtained by amniocentesis or aspiration of fluid in the course of cesarean delivery for accepted obstetric indications from patients of the obstetric services of the Albany Medical Center Hospital. Samples with blood contamination and those that were very cloudy after centrifugation were excluded. The results obtained with the new test were not available to the physician determining fetal respiratory outcomes. Neonatal respiratory distress was determined on the basis of neonatal requirements for supplemental oxygen for at least 24 hours and characteristic chest radiographs (presence of a diffuse reticular-granular pattern and air bronchograms). Transient tachypnea of the new-

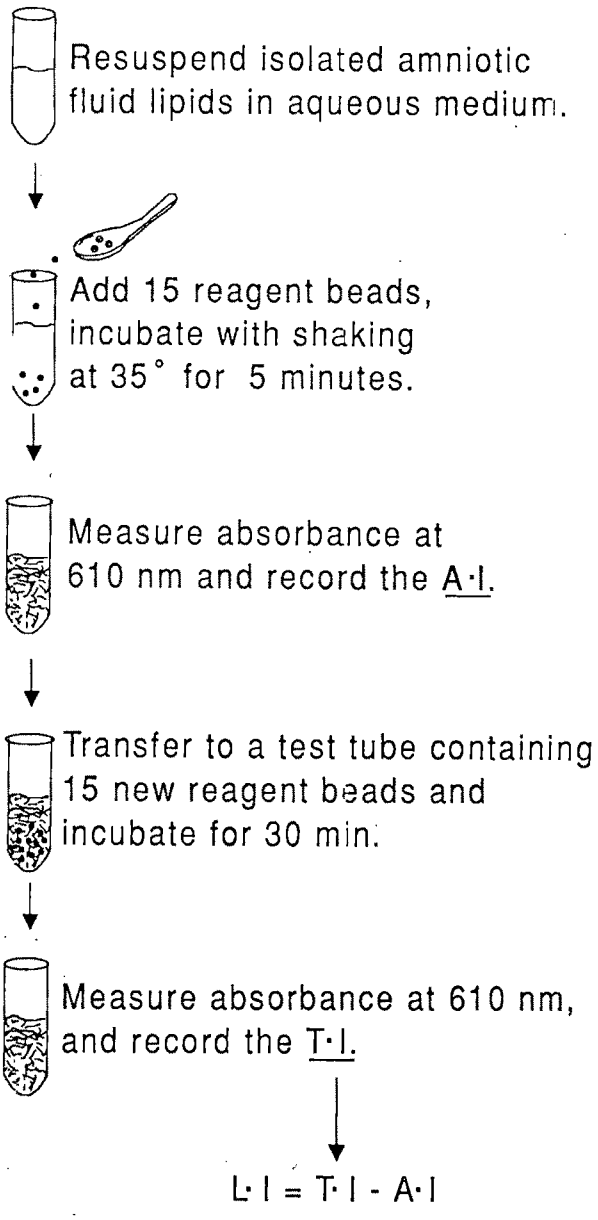

Fig. 1. Schematic for analysis of amniotic fluid specimen with modified test (differential incubation procedure).

born was determined by requirement for <12 hours of ventilatory assistance and the absence of radiographic findings.

One hundred seventeen patients were tested with the new test. The clinical performance of the assay was assessed from diagnoses of 94 amniotic fluid specimens (RDS prevalence of 16%) that were collected within 3 days of delivery. Gestational ages, which were evaluated from menstrual history, ultrasonography, and Dubowitz scores, ranged between 27 and 40 weeks. Nine of the newborns had transient tachypnea of the newborn; seven patients had premature rupture of membranes and 25 were diabetics. Of the 94 patients, 78 (RDS prevalence of 18%) were analyzed by thin-layer chromatography and the L/S ratio was determined.

Fetal lung maturity assessment. Phospholipids were extracted from 1.5 ml amniotic fluid that was centrifuged at 200*g* for 5 minutes by two volumes of chloroform and one volume of methanol. The organic phase was placed in a 16 × 125 mm test tube and the solvent was removed by evaporation under nitrogen. The phospholipid residue of the organic phase was resuspended in 2.0 ml water by a 2-minute vortexing.

Reagent-glass beads were prepared by using a dye reagent precipitated from a mixture of 8×10^{-5} mol/L cetyltrimethylammonium bromide and 5.5×10^{-5} mol/L coomassie brilliant blue. The blue precipitate was dissolved in 5 ml acetone, and the solution was added to 50 gm of 3 mm glass beads (Kimax, Kimble Science Products, Vineland, N.J.). The reagent was adsorbed onto the beads by evaporating the solvent to dryness.[7]

A scheme for amniotic fluid analysis for fetal lung maturity is shown in Fig. 1. Fifteen reagent beads were added to a 2.0 ml sample and incubated for 5 minutes at 35° C with 250 rpm shaking. The absorbance of the blue solution at 610 nm was measured and represented as A·I. The solution was then transferred to another test tube containing 15 new reagent beads; incubation continued for another 30 minutes. The absorbance at 610 nm at the end of this interval reflected T·I. L·I was obtained by subtracting the value of A·I from that of T·I.

Thin-layer chromatography for the L/S ratio determinations was performed as before.[7] L/S ratio >2.0 was taken to indicate maturity. In general, thin-layer chromatography of the lipid extract of the amniotic fluid sample was performed first. The fluid was then stored at −20° C, up to several weeks, before analysis by the colorimetric assay. Results are a mean of duplicated determinations.

A Beckman CDS-200 densitometer was used for the L/S ratio determination and a Perkin Elmer Lambda 4B (Perkin Elmer Corp., Norwalk, Conn.) spectrophotometer for absorbance measurements. Statistical analysis and clinical performance evaluations were performed with the statistical capabilities of RS/1 and an IBM-compatible microcomputer. Variation is indicated by standard deviation. Significant differences were determined by χ^2 analysis, and for small sample size the χ^2 statistic with correction[8] was used.

Results

Fetal lung maturity was assessed with an improved procedure based on the specific solubility of a novel dye reagent in an amniotic fluid phospholipid sample with two incubation intervals. The modified assay circumvented the use of organic solvent required previously[7] for the simultaneous estimation of lecithin and anionic phospholipids, such as phosphatidylinositol and phosphatidylglycerol, in amniotic fluid. Reagent-glass beads were incubated in a water suspension

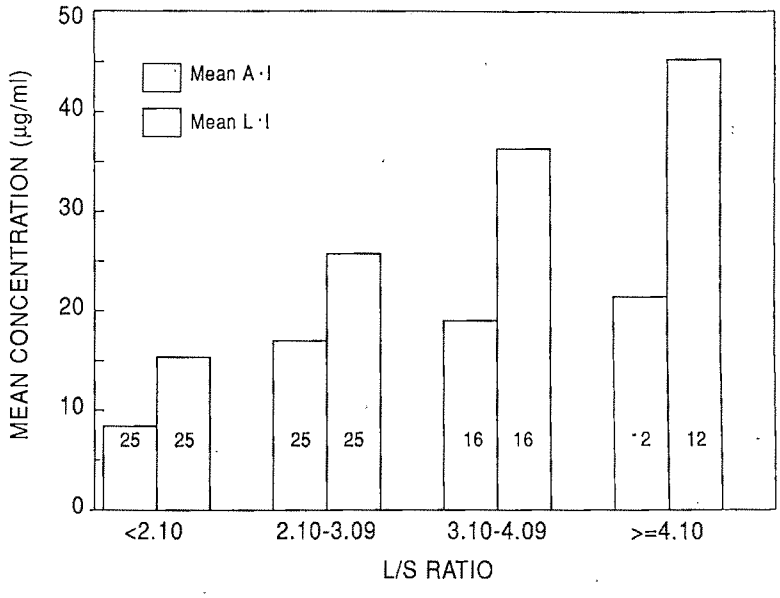

Fig. 2. Correlation between results of new assay (A·I and L·I) with different ranges of L/S ratio. Number of patients tested at each L/S ratio range indicated inside *bars*.

of isolated amniotic fluid lipids for 5 minutes and 30 minutes (Fig. 1). The anionic phospholipids were estimated after the first incubation interval, whereas the lecithin content was measured after the second interval (Fig. 1).

The absorbance values ranged between 0.14 and 0.75 for 95% of the specimens tested in this study. The mean coefficient of variation percentages for the 610 nm absorbance measurements at each incubation interval within a run at different levels of amniotic fluid maturity were 6.9% ± 1.7% and 9.6% ± 2.0% and between runs 6.6% ± 1.5% and 8.6% ± 1.8%, respectively. Proteins, such as unlipidated bovine serum albumin (50 μg/ml), cholesterol (50 μg/ml), lysophosphatidylcholine (20 μg/ml), and sphingomyelin (20 μg/ml) produced very little absorbance (<0.05) under the conditions of the assay.

Absorbance values of the new colorimetric test were converted to phospholipid concentration with appropriate calibration plots determined for each batch of reagent-glass beads preparation. Three clinical indexes—A·I (anionic phospholipid index), L·I (lecithin index), and T·I (total phospholipid index)—were determined simultaneously. The relation between A·I and L·I with different L/S ratios was illustrated in Fig. 2. A trend of increasing index values with the L/S ratio was evident. Nine patients with L/S ratios (1.5 ± 0.4) indicating immaturity had a corresponding mature A·I (14.4 ± 5.2 μg/ml). Just one of these patients had RDS. Eight patients had immature L/S ratios (1.5 ± 0.4) and a corresponding mature L·I (23.5 ± 5.7 μg/ml). Two of these patients had RDS.

Diagnostic cutoff points for A·I and L·I were obtained with 94 specimens that were collected within 3 days of delivery. Cutoff points were selected by minimizing the number of false results in predicting respiratory outcome, by maximizing the corresponding sum of sensitivity and specificity, and by a receiver-operator characteristic curves analysis[8, 9] (Fig. 3). To define a positive test as predictive of RDS,[10] the selected optimal

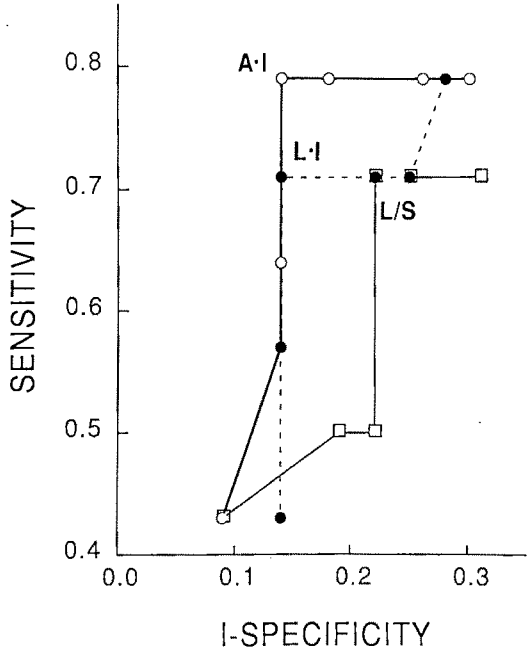

Fig. 3. Receiver-operator-characteristic curves for A·I and L·I of new assay and for L/S ratio. Sensitivity and 1-specificity were calculated at various cutoff points, and respective optimal cutoff points are shown. (Number of samples analyzed by both methods were same [n = 78].)

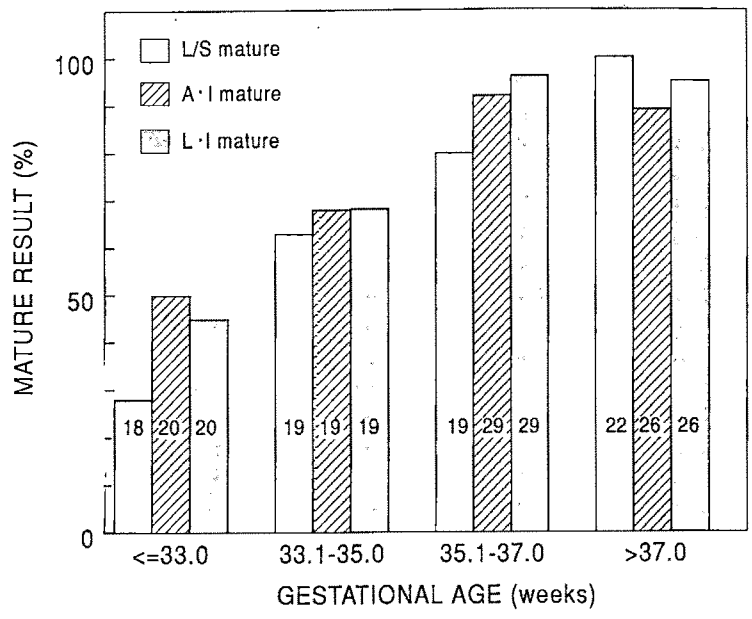

Fig. 4. Correlations of new test results and L/S ratio with gestational age. Number of patients assayed with each test at each gestational age range are indicated inside *bars*.

Table I. Clinical performances of new assay (n = 94) and L/S ratio (n = 78) in predicting RDS

*Clinical parameter**	*Diagnostic index*			
	A·I	*L·I*	*AL·I†*	*L/S*
Specificity	89 (86)	89 (86)	93 (92)	78
Sensitivity	80 (79)	73 (71)	73 (71)	71
Negative predictive value	96 (95)	94 (93)	96 (95)	93
Positive predictive value	57 (55)	55 (52)	71 (69)	42
Efficiency	87 (85)	86 (83)	90 (90)	77
False-positive results (%)	11 (14)	11 (14)	7 (8)	22

Diagnostic indexes A·I, L·I, and AL·I are defined in the text. Values in parentheses were obtained with the L/S ratio study population (n = 78).

**p*, Positive for RDS; *N*, negative for RDS; *FP*, immature result and no RDS; *TP*, immature result and RDS; *FN*, mature result and RDS; *TN*, mature result and no RDS; specificity = $\frac{TN}{TN + FP} \times 100$; sensitivity = $\frac{TP}{TP + FN} \times 100$; negative predictive value = $\frac{TN}{TN + FN} \times 100$; positive predictive value = $\frac{TP}{TP + FP} \times 100$; efficiency = $\frac{TP + TN}{All} \times 100$; percentage of false-positive results = $\frac{FP}{FP + TN} \times 100$.

†A positive test with AL·I was indicated only if both A·I (≤7.5 μg/ml) and L·I (≤19.0 μg/ml) were below their cutoff points.

cutoff values were 7.5 and 17.0 μg/ml phospholipid, respectively. Fifty-four specimens were treated by the differential-incubation assay, and 40 specimens were analyzed by the earlier procedure.[7]

The percentage of mature results (samples with values higher than cutoff points) assessed by both the new indexes and by the L/S ratio increased with gestational age (Fig. 4). The percentages of healthy newborns, as determined by respiratory outcomes, at each gestational age group were 45% before 33 weeks, 84% between 33 and 35 weeks, 96% between 35 and 37 weeks, and 100% after 37 weeks' gestation. Before 33 weeks' gestation, the percentage of mature results with the new test (Fig. 4) was in excellent agreement with the outcome data. In contrast, the percentage of mature results according to the L/S ratio was much lower than the actual percentage of healthy outcomes. This is consistent with the large number of false-positive results that were obtained with this ratio before and at 33 weeks' gestation.

The diagnostic performance of the new test was evaluated by determining the specificity, sensitivity, predictive values, efficiency, and percentage of false-positive results (Table I). The diagnostic efficiency of all indices

Table III. Clinical performances of new assay and L/S ratio in predicting RDS before and at 36 weeks' gestation and in a region of transitional L/S ratios

	Gestational age ≤36 wk		*2.5 ≥ L/S ≥ 1.6*	
	AL·I (n = 39)	*L/S (n = 37)*	*AL·I (n = 22)*	*L/S (n = 22)*
Efficiency (%)	77	59	82	50
False-positive results (%)	16	46	13	53

The performance of AL·I (parameters defined in Table I) is compared with that of the L/S ratio.

was above 86%, and the specificity was above 89%. The specificity and the predictive value of an immature (positive) result improved when a combined index of A·I and L·I, designated as AL·I (RDS was predicted only if both A·I [≤7.5 μg/ml] and L·I [≤19.0 μg/ml] were below their cutoff points), was used (Table I).

The clinical performance of the new test was compared with that of the L/S ratio by evaluating the results obtained from analyses of amniotic fluid specimens with both tests ($n = 78$). The specificity and the predictive value of a positive result were higher for the new test than with the L/S ratio (Table I). The number of false-positive results was significantly ($p < 0.02$) lower for the AL·I (8%) than for the L/S ratio (22%) (Table I).

The receiver-operator characteristic curves of the new indices and the L/S ratio crossed below 0.5 sensitivity, and the portion of the curve of greatest clinical interest[8] is shown in Fig. 3. The new test curves were closer to the upper left corner of the graph than the L/S ratio curve, suggesting that the new test is superior. The 1-specificity (false-positive rate) of the new test was compared statistically with that of the L/S ratio at a fixed sensitivity with paired samples.[8] At 0.79 sensitivity the corresponding false-positive rates were 0.14 with the A·I (≤7.5 μg/ml) and 0.31 with the L/S ratio (<2.5), indicating that the new test performed better ($p < 0.03$) than the L/S ratio.

The clinical performance of the new assay changed very little with samples collected within 2 or 4 days of delivery (Table II). In all but one of the false-negative results, RDS was classified as mild, and the pregnancies had at least one other complication including twin, preterm labor, amnionitis, premature rupture of membranes, or preeclampsia. These patients also had a mature result by optical density measurements ($OD_{650} > 0.15$) with a mean OD_{650} of 0.38 ± 0.16.

The test performed well under demanding conditions. The clinical performances of the new test and the L/S ratio, in patients up to and including 36 weeks' gestation, are given in Table III. The number of false-positive results was almost threefold lower with the AL·I than that obtained with the L/S ratio (Table III). The AL·I was significantly better ($p < 0.05$) than the L/S ratio in indicating maturity. The specificity and sensitivity of the test were 84% and 71% as compared with 54% and 69% for the L/S ratio. In addition, for patients with transitional L/S ratios between 1.6 and 2.5, the percentages of false-positive results were 13% and 53% with the AL·I and the L/S ratio, respectively (Table III).

Comment

The new colorimetric test for antenatal assessment of fetal lung maturity is based on the specific solubility of a single-solid dye reagent, adsorbed on glass beads, in an aqueous solution of amniotic fluid phospholipids. This reagent can be stored at room temperature for months and eliminates the problems associated with labile biologic reagents. The new test can be performed

by someone without extensive technical expertise, takes less than an hour to complete, and is quantitative and cost-effective.

The ability to express results quantitatively may contribute to improving the prevailing poor interlaboratory reproducibility in predicting RDS. The sum of L·I and A·I of a mature result was higher than 25 μg/ml phospholipid, in agreement with previous reports.[11] The cutoff points ratio (L·I/A·I) was 2.3, which corresponds to about 70% lecithin and 30% anionic phospholipid.

Fetal lung maturity assessment is complex and involves many complicating factors. Many of the widely used methods for predicting RDS are based on the measurement of a single component or property of lung surfactant. The new test is based on both the surface properties and the phospholipid composition of lung surfactant. At least two different diagnostic indexes corresponding to different classes of phospholipids were determined. The performance of the test is expected to be enhanced by its provision for quantitative and simultaneous determination of more than one amniotic fluid phospholipid index, as shown by a relatively high predictive value of an immature result (Table I).

The clinical usefulness of the new test was expressed by a high specificity, a high percentage of correct diagnoses, and a significantly lower percentage of false-immature results than that obtained with the L/S ratio. This suggests that this new promising test may be a good alternative to current methods for predicting RDS.

We thank Donald S. Berns for his assistance, Paul Sherman for performing the thin-layer chromatography measurements, Bernard R. Lipinskas for his help in installing our computer, and Andrew A. Reilly for his help with the statistical analysis.

Discussion

Dr. Charles M. Stedman, New Orleans, Louisiana. I distinctly recall the clinical laboratory class that day at medical school in 1972. The instructors had chosen the L/S ratio as the project for the afternoon, and we were the first class to participate. The test had been introduced in 1971 by Gluck et al.,[1] who reported a technique to screen for fetal pulmonary maturity. We should all pause to consider that this article is one of those rare medical works that has continued as the gold standard 20 years after initial presentation.

The impact of the L/S ratio in the 1970s was as a reliable screening test. Obstetricians finally had a tool to prevent instances of iatrogenic prematurity at repeat cesarean section. The pediatric literature of the day described unintended prematurity accounting for 10% to 15% of admissions to intensive care nurseries. During a time when urine pregnancy tests were relatively insensitive, ultrasonography was used sparingly, and scheduled repeat cesarean section was the norm, the L/S ratio served as a safeguard. Its clinical utility was to predict the absence of RDS.

In the 1990s our needs are somewhat different. Use of the L/S ratio as a screening test is less frequent. Urine pregnancy tests are positive when a menstrual period is 1 day late and first-trimester sonograms establish the gestational age within narrow confidence limits. In spite of some physicians thinking vaginal birth after previous cesarean section means "very bad alternative to cesarean," many patients are allowed to labor.

Currently it is my observation that we use fetal lung maturity testing more as a semiquantitative test than as a screening test. In cases of fetal distress we attempt to weigh the likelihood of RDS and the associated complications against the risk of continued in utero existence. When we have patients experiencing preterm labor, our knowledge of the L/S ratio can affect the level of intensity of tocolytic treatment. Harvey et al.[2] have reviewed 385 patients delivered within 72 hours of sampling. For values between 1.5 and 2.0, 40% developed RDS; for values <1.5, 73% developed RDS. In most laboratories, an L/S ratio <1.0 assures RDS. Unfortunately, these numbers are variable from institution to institution because of the interlaboratory variability of the ratios.

Almog and associates have described a technique with the apparent advantages of being less labor inten-

sive; less time-consuming, more reproducible from laboratory to laboratory, and more convenient to the obstetrician because of the smaller sample size required. The critical portion of this article concerns the fewer false positives (i.e. false immature results) in the <33 weeks group. Fifty percent of samples were mature by the anionic index, yet only 28% were mature by the L/S ratio. Dr. Almog provides us with the hope of identifying more of the fetuses who will not develop RDS. We could spare more women from what I call brutal tocolysis. I am referring to patient who has developed premature labor recurrently and may require multiple courses of intravenous tocolytics with all the associated side effects.

To critically analyze the <34 weeks group, I think obstetricians would like to know more clinical details. What were the corresponding L/S ratios for the patients mature by the anionic index but immature by the L/S? Were most 1.8 to 1.9 or were they much lower? Was gestation age assigned by early ultrasonography or by Dubowitz scores? What percentage of patients had received glucocorticoids to enhance pulmonary maturity?

Certainly amniotic fluid analysis is not mandatory before all preterm deliveries. The pregnant woman with severe hypertension is delivered for maternal reasons. The delivery of a fetus with severe growth retardation and reversed Doppler flow in the cord is not going to hinge on the L/S ratio. It's the patients at 32 to 34 weeks requiring repetitive or intense tocolysis that are difficult for all of us.

In summary, this manuscript was well written and targeted a clinical area where improvement is needed. My only major criticism is that 40 of 96 samples were analyzed by the previously reported phase-partition procedure and lumped with 54 samples analyzed by the newer method. Such a change in methodol makes it difficult to apply statistical analysis. Nevertheless, the false-immature values in the <34 weeks group were much less frequent using the anionic index. I find myself feeling like most fans of the 5-0 New Orleans Saints—the initial percentages are exciting, but we need more numbers before allowing unbridled enthusiasm.

DR. ROBERT C. KAUFMANN, Springfield, Illinois. The authors of this paper have made claims that have a high probability of not being true. This has occurred because of a study design that is at risk for a type 1 error and because of a lack of proper presentation and analysis of data. The authors should not feel lonely, because this seems to be a common problem with many papers.

The receiver-operator curves for this paper are misleading in that the scales of the x and y axes are not equal. What appears to be an obvious difference in the receiver-operator characteristic curves vanishes when the scales are equalized. In fact, statistical analysis of these curves reveal that they are essentially identical with the area underneath the A·I, L·I, and L/S curves, 0.15, 0.12, and 0.12, respectively, and the standard error of each curve is 0.04. Therefore the receiver-operator curves do not illustrate the superiority of the new indices.

In the design of this study the results of the L/S ratio were available to the obstetrician for use in the management of the patient, whereas the results of the new indices were not available. This leads to verification bias, which is inherent in most studies of "new" methods to predict RDS. (1) Because most babies that have low L/S ratios will not be delivered, (2) because most babies that have high L/S ratios will be delivered, and (3) because only those cases with delivery within 3 days of specimen collection are analyzed, there is a bias for delivering those infants who have negative test results over those who have positive test results. Such bias causes the false-positive and false-negative rates of the L/S to be overestimated and those of new indices to be underestimated.[1] By using the undelivered cases one can mathematically correct for verification bias. In the interest of time and to not totally bore the majority of this audience, the details of these corrections will not be pursued. Suffice to say that such a lack of correction for verification-bias causes the conclusions of this study to be suspect. Those desiring to pursue this matter are encouraged to read an article by Hunink et al.[1] entitled, "Testing for fetal lung maturity."

The authors have further compounded the error of verification bias by an error in study design. There is an inequality in the number of cases and the rate of RDS in the cases that were analyzed by the two methods. There were a total of 94 cases analyzed by the new method, although only 78 of these were analyzed by the traditional L/S method. In these 78 cases the rate of RDS was 18% (14 cases), whereas in the remaining 16 cases analyzed only by the new indices the rate of RDS was only 6% (one case). Although these rates are not significantly different, the addition of these 16 samples to L/S analysis could significantly change the results and conclusions of this study. If, in these 16 patients, the L/S ratio correctly predicted the one case of RDS (the probability of correct prediction is 71%) and correctly predicted all of the non-RDS cases (a probability of 78%), the L/S ratio would have statistically similar results as all of the new indices. Such a finding would cause the author to state that the new indices are not superior in predicting either RDS or the lack of it.

Although I have been somewhat critical of this paper, I do not want Dr. Almog and his colleagues to feel lonely. We are having to deal with the same problems of study design and verification-bias in trying to develop a "new" test for fetal lung maturity in our institution. Although little is made of it in the paper, the author raises a point (one we have also begun raising) that sometimes we want a test that minimizes the risk

of RDS and other times we want a test that maximizes the lack of risk for RDS. The combination of the new indices that the author has proposed may be helpful in this regard. I would like to encourage the authors to continue to pursue this research and to try to correct the errors that I have elucidated. Even if the new indices are only equal to the traditional L/S ratio in predicting RDS but they can both minimize the risk of RDS and maximize the lack of risk for RDS, the simplicity and reproducibility of the new method could prove to be a valuable tool for clinical use.

REFERENCE

1. Hunink M, Richardson D, Doubilet P, Begg C. Testing for fetal pulmonary maturity. Med Decis Making 1990;10: 210-1.

Dr. Daniel Rightmire, Springfield, Illinois. I would like to know if the authors have any information about the performance of their test in the presence of meconium, bilirubin, or oxyhemoglobin pigments.

Dr. Almog (Closing). The purpose of this manuscript was to catalyze and encourage the use of the test in clinical laboratory settings. I agree with Dr. Stedman that the test should be studied further before it is used in the management of patients. I also agree that the most critical gestational age group is 32 and 33 weeks. Later on, RDS is not as important and it is not a critical issue in patient management.

I thank Dr. Kaufmann for his very constructive criticism. The scales of the receiver-operator characteristic figure are somewhat misleading, but they do not affect the relative location of each curve. I did not calculate the areas under the curves but I am going to look into it. However, the specificity and the sensitivity show that our test is at least as good if no better than the L/S ratio.

Concerning the question of different population sizes, the performance of the new test, using the L/S ratio population, was still significantly better than the ratio in indicating maturity. This was also indicated in the slide describing the performance of both tests before 36 weeks' gestation.

The bias that may result from the fact that the L/S ratios were known to the physicians and our test results were not known is a problem that anyone developing a new test has to face. However, both tests were performed on the same high-risk heterogeneous population. Each clinical complication may affect the verification and occurrence of RDS differently. The L/S ratio was not consulted in many cases and was one of many factors that were taken into consideration in the decision making of patient management. In this situation verification bias analysis is complex, and the outcome of such analysis may not be clear.

A question was asked about the performance of the test in the presence of meconium, bilirubin, or bloodstain. Very little was done in this area but we did analyze several contaminated samples and the test performed quite well.

It should be noted that the test measures the amount of anionic phospholipids. Anionic phospholipids are not present, except in very small amounts, in meconium and blood, whereas lecithin and sphingomyelin, which are used in the L/S ratio, are present in these fluids. Therefore our test should perform much better than the L/S ratio, but we have not studied as many samples as we wish to study.

Urinary incontinence: Correlation of history and brief office evaluation with multichannel urodynamic testing

Robert L. Summitt, Jr., MD,[a] Thomas G. Stovall, MD,[a] Alfred E. Bent, MD,[b] and Donald R. Ostergard, MD[b]

Memphis, Tennessee, and Long Beach, California

OBJECTIVE: Patients' histories of urinary incontinence and the results of several standard clinical tests were correlated with final diagnoses obtained by multichannel urodynamic testing. We used a combination of clinical test results to predict the final diagnoses.

STUDY DESIGN: Ninety consecutive women with a primary complaint of urinary incontinence completed a standardized questionnaire and underwent a structured clinical examination consisting of several standard clinical tests. Each patient later underwent multichannel urodynamic testing to obtain a final diagnosis.

RESULTS: Although the symptoms of stress incontinence were significantly associated with genuine stress incontinence and mixed incontinence, overlap in patients with detrusor instability did not allow the histories to be useful diagnostically. The only clinical tests showing significant association with the final diagnoses of incontinence were the cough stress test and single-channel medium-fill cystometry. Reliable prediction of the urodynamic diagnosis of incontinence could not be achieved with either of these two tests or with a combination of variables obtained by discriminant analysis.

CONCLUSIONS: Women with complaints of urinary incontinence, especially those for whom surgery is contemplated, should undergo complete urodynamic evaluation when it is available. (Am J Obstet Gynecol 1992;166:1835-44.)

Key words: Urinary incontinence, urodynamic testing

The treatment of a female patient with a primary complaint of urinary incontinence is often based on history alone. Because history correlates poorly with the objective cause of urinary incontinence, therapy directed by a patient's complaints can be incorrect.[1-6] However, when the clinician performs an objective evaluation of incontinence, he or she may be unfamiliar with the methods of office testing or may refer the patient for highly technical and expensive urodynamic testing.

We present our investigation of urinary incontinence, in which we studied the correlation of the patient's history and several selected widely available clinical tests with the final diagnosis of urinary incontinence determined by multichannel urodynamic testing. The objective of this investigation was to correlate the patient's history of incontinence with the final diagnosis on the basis of urodynamic testing and to compare this urodynamic diagnosis with results of several clinical tests that can be performed in any practitioner's office. In addition, we attempted to make a predicted diagnosis of urinary incontinence that was based on selected clinical tests, and we compared this diagnosis with that obtained by multichannel urodynamic testing. Our aim was to determine what should be included in a minimum office evaluation and to identify those patients who require multichannel urodynamic testing.

Materials and methods

This prospective study was begun in September 1987 at the University of California, Irvine and Memorial Medical Center, Long Beach, and was continued after July 1988 until June 1991 at the University of Tennessee, Memphis.

Ninety consecutive female patients were evaluated for a primary complaint of urinary incontinence. Their ages ranged from 21 to 76 years (mean 52.8 ± 12.0 years) and the mean parity was 3.1 ± 1.8 (range 0-10). The racial distribution showed 72 white patients (80.0%), 16 black patients (17.8%), and 2 Hispanic patients (2.6%). At the first visit all patients gave a detailed history and underwent a standardized group of clinical tests that resulted in a preliminary diagnosis of incontinence.

In addition to demographic data, the history included a 24-hour voiding diary and a group of ques-

Table I. Final diagnoses for 90 patients determined by multichannel urodynamic testing

Genuine stress incontinence	38	42.2
Detrusor instability	17	18.9
Mixed incontinence	24	26.7
Urethral instability	2	2.2
Overflow incontinence	1	1.1
TOTAL	90	100

tions that were selected from our standard questionnaire[7] to differentiate genuine stress incontinence from detrusor instability or other disorders of overactive detrusor function. Questions were read directly from the data recording sheet to avoid questioning bias. The questions were as follows:

1. Do you lose urine during coughing, sneezing, or vomiting?
2. Do you lose urine with walking, running, straining down, or changing positions?
3. When you are passing urine, can you usually stop the flow?
4. Do you lose control and pass a large amount of urine when you cough, sneeze, or strain?
5. Do you always have an uncomfortably strong need to pass urine before you empty your bladder?
6. Do you lose urine before reaching the toilet?
7. How many times do you void during the night after going to bed?

Questions 1 and 2 were thought to predict genuine stress incontinence and questions 3 to 7 were considered to predict detrusor overactivity.

The clinical examination and tests were based on a standard evaluation used in our urogynecology clinic but were structured so that clinicians could perform these tests in their offices with minimal equipment and previous instruction. The clinical evaluation included a catheterized urine sample used to determine residual volume and to perform culture, neurologic and pelvic examinations, a Q-Tips cotton swab test, a cough stress test, and a medium-fill, single-channel water cystometrogram. A normal residual urine result was defined as ≤ 50 ml. A positive urine culture was $\geq 10^5$ colonies per milliliter of urine. A mild cystocele was defined as the descent of the anterior vaginal wall to the midplane of the vagina while the patient was straining in the lithotomy position. A moderate cystocele was defined as the descent of the anterior vaginal wall through the midplane of the vagina but not beyond the introitus, and a severe cystocele was defined as the descent anterior vaginal wall outside the vaginal introitus. After the pelvic examination, a previously described Q-Tips cotton swab test was performed.[8] A maximum straining angle of ≥ 30 degrees from the horizontal was defined as a positive Q-Tips cotton swab test and was considered indicative of urethral hypermobility. The cough stress test was performed while the patient was in the standing position and had a symptomatically full bladder that contained at least 300 ml of fluid. The patient was asked to cough vigorously three times, and the test result was considered positive if leakage from the urethra was observed. A medium-fill, single-channel cystometrogram (Endotek OM-3 Max Digital Urodata monitor, Medical Engineering Corp., Racine, Wis.) was performed with a three-way 16F Foley catheter and saline solution at 38° C when the patient was standing. The patient was asked to cough and heel bounce at every 100 ml infused. Maximum bladder capacity and uninhibited detrusor contractions were observed. A detrusor contraction was defined as a sustained pressure rise of >15 cm H_2O while the patient inhibited voiding and did not execute Valsalva's maneuver.

At least 1 week after the initial evaluation, all patients underwent multichannel urodynamic testing with a six-channel recorder (Urolab model 1106, Life-Tech, Inc., Houston) and microtip pressure transducers (models PUPC-780 and PUPC-380, Life-Tech).[9] If a positive urine culture was found at the initial evaluation, urodynamic testing was delayed until a repeat culture showed resolution of the infection. Static and stress urethral pressure profiles were obtained when the patient was in both the supine and the sitting positions. Multichannel cystometry was performed when the patient was standing. Genuine stress incontinence was defined by pressure equalization on the stress urethral pressure profile in the absence of detrusor activity. Mixed incontinence was defined as genuine stress incontinence and detrusor instability in the same patient. All terms conform to the recommendations of the International Continence Society unless specifically stated.[10]

Demographic data, history, and clinical testing were correlated with the final urodynamic diagnoses. Independent variables were analyzed by either the χ^2 test or two-tailed Fisher's exact test, and $p < 0.05$ was considered statistically significant. The reproducibility of the predicted diagnoses by multichannel urodynamics was analyzed by the κ statistic.[11] A κ value of >0.75 denoted excellent reproducibility and κ values of ≥ 0.4 and ≤ 0.75 denoted good reproducibility. A κ value of <0.4 indicated poor reproducibility.

To define a meaningful combination of information that would allow the most accurate prediction of incontinence, we used a discriminant analysis program

Table II. Frequencies of answers to questions thought to discriminate diagnoses of incontinence

Question No.	Patients answering "yes" (%)			
	Genuine stress incontinence (n = 38)	*Mixed incontinence (n = 24)*	*Detrusor instability (n = 17)*	*Significance*
1. Stress incontinence with cough, sneeze, vomiting	94.7	100	70.6	$p = 0.003$
2. Stress incontinence with walking, running, etc.	100	91.7	52.9	$p < 0.001$
3. Ability to stop urine flow	57.9	41.7	52.9	NS
4. Large urine loss with cough, sneeze, etc.	29.0	50.0	41.2	NS
5. Urgency	23.7	37.5	58.8	$p = 0.041$
6. Urge incontinence	76.3	91.7	94.1	SN

NS, Not significant.

to determine the variables. When these variables were obtained, the most discriminating combination was determined and was used to predict the final diagnosis.

Results

The final diagnoses obtained by urodynamic testing are shown in Table I. No statistically significant association was found between age, parity, or race and the final diagnosis.

To analyze individual tests and data associated with the most common forms of incontinence, we further evaluated only those patients who had a final diagnosis of genuine stress incontinence, detrusor instability, or mixed incontinence.

Twenty-seven women studied had undergone a hysterectomy. There was no significant association between previous hysterectomy and incontinence. Previous surgery to correct incontinence had been performed in 26 patients. No statistically significant association was found between the type or number of procedures to correct incontinence and the final diagnosis of incontinence.

Responses to questions that distinguish genuine stress incontinence from detrusor instability are shown in Table II. The percentages of patients with genuine stress incontinence or mixed incontinence who answered "yes" to questions 1 and 2 were statistically different from those of patients with detrusor instability. However, of patients with only detrusor instability, 70.6% and 52.9% answered "yes" to questions 1 and 2, respectively. There was also a statistically significant difference in the incidence of urgency between patients with genuine stress incontinence and those with detrusor instability. The history of nocturia was not included in Table II because it was a continuous variable. No significant association was shown between the number of voids during the night and the final diagnosis.

Results of the six clinical tests and their associations with final urodynamic diagnoses are shown in Table III. The only tests that showed statistically significant associations were the cough stress test and single-channel standing cystometrogram. The cough stress test result was positive more frequently in patients with genuine stress incontinence or mixed incontinence, regardless of whether these groups were analyzed individually or together. It is of note that 17.7% of patients with detrusor instability demonstrated urine loss when they coughed. Uninhibited detrusor contractions during single-channel medium-fill cystometry were strongly associated with a final diagnosis of detrusor instability and/or mixed incontinence. However, 10.5% of patients with genuine stress incontinence had a positive screening cystometrogram. No statistically significant association was noted between the final diagnosis and a moderate to severe cystocele or urethral hypermobility.

The ability of a predicted diagnosis that is based on the cough stress test result and the single-channel cystometrogram to be reproduced by multichannel urodynamics is shown in Table IV. Good (but not excellent) reproducibility between predicted and final diagnoses was determined by κ value of 0.615. No patient with a predicted diagnosis of genuine stress incontinence was found to have only detrusor instability on urodynamic testing, but 17.9% did have mixed incontinence. No patient with a predicted diagnosis of detrusor instability was found to have genuine stress incontinence after urodynamic evaluation; however, 6.7% of those patients had mixed incontinence, and in another 13.3% no incontinence could be demonstrated. Urodynamic evaluation indicated that 50% of patients predicted as having no incontinence had etiologic factors for urine loss.

Discriminant analysis of the predictive data produced a function composed of six variables. The following six variables, in combination, were judged as discriminating: question 1, question 2, question 6, a history of one or more incontinence procedures, the cough stress test result, and the single-channel cystometrogram. In their most discriminating combination the best prediction of

Table III. Results of clinical tests in 79 patients undergoing multichannel urodynamic testing

Clinical test	*Final diagnostic groups with positive clinical test results (%)*			
	Genuine stress incontinence (n = 38)	*Mixed incontinence (n = 24)*	*Detrusor instability (n = 17)*	*Significance*
Urine culture >100,000 colonies/ml	5.3	8.3	5.9	NS
Moderate to severe cystocele	44.7	50.0	70.6	NS
Residual urine >50 ml	10.5	8.3	17.7	NS
Positive cough stress test result	89.5	91.7	17.7	$p < 0.001$
Positive Q-Tips cotton swab test result	84.2	91.7	76.5	NS
Evidence of detrusor instability on standing cystometrogram	10.5	70.8	88.2	$p < 0.001$

NS, Not significant.

Table IV. Reproducibility between predicted diagnosis, determined by cough stress test and single-channel cystometrogram, and final urodynamic diagnosis

Predicted diagnosis	*Final urodynamic diagnosis*							
	No incontinence (n = 8)		*Genuine stress incontinence (n = 38)*		*Mixed incontinence (n = 24)*		*Detrusor instability (n = 17)*	
	No.	*%*	*No.*	*%*	*No.*	*%*	*No.*	*%*
No incontinence ($n = 10$)	5	50.0	3	30.0	0	0	2	20.0
Genuine stress incontinence ($n = 39$)	1	2.6	31	79.5	7	17.9	0	0
Mixed incontinence ($n = 23$)	0	0	4	17.4	16	69.6	3	13.0
Detrusor instability ($n = 15$)	2	13.3	0	0	1	6.7	12	80.0

A κ value of 0.615 indicates good reliability ($p < 0.001$).

genuine stress incontinence reached 89.5%. The best combinations of these variables that accurately predicted mixed incontinence or only detrusor instability reached 66.7% and 76.5%, respectively.

Comment

The aim of this study was to analyze the association of a patient's history and a group of predictive clinical tests with a final diagnosis of urinary incontinence determined by multichannel urodynamics. We hoped to provide the clinician with a practical and accurate method of evaluating patients with urinary incontinence and defining those patients who should undergo more extensive urodynamic testing. We found that a patient's history correlated poorly with the final diagnosis of incontinence. Only two clinical tests, the cough stress test and single-channel cystometrogram, provided reliable predictive information. Even so, reproducible prediction of urinary incontinence was not always possible with these two tests or a derived group of discriminant variables.

The patient's history has repeatedly been shown to be an unreliable predictor of the underlying cause of urinary incontinence.[1-6] Walters and Shields[3] and Cardozo and Stanton[1] showed a strong association between the symptom of stress incontinence and the final diagnosis of genuine stress incontinence. However, approximately 72% and 50%, respectively, of their patients with detrusor instability complained of stress incontinence. Our findings are very similar to those just cited. In addition, 76.3% of our patients with genuine stress incontinence related a history of urge incontinence. The patient's history must be highly sensitive and specific to be a reliable diagnostic tool. We have shown poor specificity of the history in predicting the cause of urinary incontinence. The patient's history is not useful diagnostically as a result of the high degree of overlap in findings among the various forms of incontinence. Obviously, the major fear of using the history to diagnose incontinence is that unnecessary surgery will be performed. Rather, the patient's history should be used to guide the subsequent evaluation process and to serve as a measure of the patient's disability.[1]

We found that many commonly performed objective clinical tests are of little diagnostic value. A urinary tract infection or a residual urine value of >50 ml was not associated with any particular diagnosis. However, these tests should always be a part of the evaluation of a woman who has lower-urinary tract symptoms. Investigation in the presence of a urinary tract infection, especially with invasive techniques, could worsen a patient's condition. A residual urine value can contribute

to the investigation of overflow incontinence and may be predictive of postoperative voiding difficulty, although our data are insufficient to support this. A moderate to severe cystocele and the Q-Tips cotton swab test, which are the clinical measures of anatomy, were not predictive of incontinence. Although a large cystocele has been associated with genuine stress incontinence, we found that it occurred more commonly in our patients with detrusor instability, although this occurrence was not statistically significant. In addition, there was no significant difference in the incidence of urethral hypermobility among any of the diagnostic groups. However, when the Q-Tips cotton swab test was originally described, its function was never diagnostic.[12] Rather, recent data support its value as a predictor of success with surgery to correct incontinence.[8, 13]

The cough stress test and standing single-channel medium-fill cystometrogram were the only clinical tests statistically associated with final urodynamic diagnoses. This is supported by the findings of Fischer-Rasmussen et al.,[6] who found that the cough stress test and cystometrogram were the most predictive of a battery of tests used to diagnose urinary incontinence. In spite of the statistical significance that was demonstrated in our study, the overlap in positive results brings the clinical ability to distinguish diagnoses into question. In 18% of patients with detrusor instability a cough stress test result was positive, and almost 10% of patients in the groups with genuine stress incontinence and mixed incontinence did not have leakage when they coughed. Again, the danger of basing the diagnosis on this test alone is that its results may indicate unnecessary surgery. Performing cystometrography most certainly reduces this potential. However, the single-channel cystometrogram is subject to false-positive results, and cystometry may not indicate the diagnosis of detrusor instability.[14] Repetitive testing with single-channel cystometry improves diagnostic accuracy.[15]

When we used the cough stress test and single-channel cystometrogram together to make a prediction of incontinence, we reduced the potential for inappropriate surgery: No patient with a predicted diagnosis of genuine stress incontinence had a diagnosis of detrusor instability after urodynamic testing. However, the overall reproducibility of our predicted diagnoses was limited. When we used a combination of variables obtained by discriminant analysis, we achieved no improvement in the reliability of predicting a diagnosis of incontinence. One assumption made during this study was that multichannel urodynamics always provided a correct diagnosis. To assume that urodynamic testing is infallible is naive. Constraints set by a laboratory environment may not allow the demonstration of urine loss that occurs when a patient is uninhibited in her own home.[6] This can result in false-negative diagnoses, especially that of detrusor instability.[14] A diagnosis of genuine stress incontinence that is based on urethral pressure profilometry has been questioned.[16, 17] Richardson[16] suggested that excessive urethral hypermobility may result in false pressure equalization during coughing. However, in most instances genuine stress incontinence may be validated with a stress urethral pressure profile.[9, 18] In our group of limited diagnostic techniques, multichannel urodynamics remains a valuable and accurate tool.

We have shown that the patient's history alone is unreliable in making a diagnosis of urinary incontinence. The use of specific office tests improves the reliability of a predicted diagnosis. However, when almost complete accuracy is necessary to avoid inappropriate therapy, it is our opinion that patients with complaints of urinary incontinence should, when available, undergo multichannel urodynamic testing. This is extremely important when surgery is contemplated.

Alternatively, for patients in whom the cough stress test is negative and a single-channel cystometrogram demonstrates detrusor instability, an initial trial of medical or behavioral therapy is acceptable. Urodynamic testing may be performed later if the patient fails to show improvement.

For the clinician who does not have the technical assistance of multichannel urodynamic testing, the office evaluation process that we have described, especially with a cough stress test and cystometry, should be mandatory. Improvement in urodynamic techniques is still needed and may be supplemented by videocystourethrography and pad testing. Further investigation is necessary.

Discussion

Dr. Jeffrey L. Cornella, Scottsdale, Arizona. The correlation of diagnosis made by sophisticated urodynamic studies versus that made by office evaluation is worthy of continued study. Inappropriate diagnosis or unnecessary testing is costly in several respects. The objective of testing is to avoid incorrect patient treatment. This study correlated multichannel urodynamic testing with symptom survey and office testing. The authors may be commended for a well-designed study and statistical analysis, yet several problems exist in making these comparisons with our present technology.

The authors recognized that urethral profilometry and dynamic pressure equalization may not be considered a gold standard in these comparisons. If one compares two inaccurate tests, how are the results to be interpreted? This study defines stress incontinence in the advanced testing group as dynamic pressure equalization in the absence of detrusor contraction. This may induce false-positive results. As Richardson[1] has noted, a telescoping urethra when the patient is straining may move relative to the microtransducer.

Select patients who have otherwise normal urethras but who demonstrate descent with stress incontinence benefit from routine operation. Current understanding of pressure transmission ratios, which are directly related to dynamic equalization, indicates the usefulness of these ratios in predicting the degree of surgical success postoperatively, but they cannot be used to differentiate preoperative leak versus nonleak profiles.[2] Diagnosis should be limited to those who have overt urine loss in the absence of a contracting detrusor.

In addition, in patients with detrusor instability the diagnosis may not be manifest on a given cystometrogram. Ambulatory testing may improve the percentage of patients who receive an accurate diagnosis. Continuous ambulatory monitoring studies often reveal a higher incidence of unstable bladder contractions than do isolated cystometrograms.[3]

This article follows the standard International Continence Society's definition of the requirement of a 15 cm H_2O contraction for the diagnosis of detrusor instability. When detrusor instability is compared with symptoms, 15 cm H_2O has been demonstrated to be artificial. Coolsaet et al.[4] investigated women with bladder instability and/or stress incontinence. Subthreshold instability was noted to correlate with the symptoms of urgency. Eighty-seven of 334 patients studied had subthreshold contractions. Only 7% of this population had an asymptomatic history of freedom from urgency incontinence and frequency of urgency sensation. The correlation of testing results and symptoms was much higher in these studies.

Venrooij et al.[5] have also noted a difference in the diagnosis of detrusor instability made by diuresis cystometry in comparison with that made by retrograde filling. Higher levels of instability were noted with diuresis filling, which suggests a relationship to antecedent flow through the ureter that aids the demonstration of detrusor instability.

The questions in this survey were similar yet different from those asked by Walters and Shields.[6] Future surveys with multiple discriminatory questions may be more predictive and may establish surveys that can be used in subsequent studies. Few surveys have been studied objectively. Future studies may establish the use of history as a predictor of diagnosis to a greater extent.

It was noted that 88.2% of patients with a final diagnosis of detrusor instability had a positive test result from a standing cystometrogram. In a previous study by the Long Beach group[7] that compared the standing cystometrogram with multichannel urodynamic testing, it was found that only 59.3% of those with a final diagnosis of detrusor instability on multichannel testing had detrusor instability on standing single-channel cystometry. These results, which use the same methods in the same institution, vary.

In addition, it has been demonstrated that patients who have severe cystocele may have kinking of the urethra, which prevents demonstration of stress urinary incontinence. As the prolapse is reduced, the patient manifests this diagnosis. This has been demonstrated by Richardson et al.[8] and by other investigators. The number of patients with severe cystocele was not noted in the article and it was not evident whether these patients had a reduction of the cystocele at any point during testing for possible stress incontinence. Perhaps some of these patients had urine loss at home from coughing, laughing, or sneezing as the prolapse receded; this may not have been noted on multichannel testing without manual reduction.

The statistical analysis in this article appears to be very appropriate. However, the origin of the statement

"The prediction of genuine stress incontinence reached 89.5%" is unclear. This article also states that 17.6% of patients with a final diagnosis of detrusor instability had urine loss when they were coughing, which could be a secondary effect of a concomitant contraction. It would be interesting to know the correlation of detrusor instability on multichannel testing in this group. If this correlation is not high, it also reflects the difficulty of making these determinations.

It is my impression that this article is an important contribution to the body of investigation on the question of the reliability of patient history and various testing modalities in the diagnosis of urinary incontinence. Thorough and sophisticated testing remains an essential component of patient evaluation. However, it is also my impression that we cannot conclude that office evaluation and history do not have significant predictability of diagnosis. Additional studies are needed as we increase our understanding and advance urodynamic technology.

DR. LANE J. MERCER, Chicago, Illinois. It is often difficult for a practicing physician to determine the standard of care for making a diagnosis or performing surgery. This is especially true in the preoperative evaluation of a patient with urinary incontinence. Although multichannel urodynamic testing has been shown to be the most reliable preoperative predictor of successful postoperative surgical correction of stress urinary incontinence, this technique remains expensive and is not readily available to all practitioners. Indeed, many experienced clinicians state that they can diagnose genuine stress incontinence from the patient's history and physical examination. With these diagnostic methods they can limit the referrals for multichannel urodynamic evaluation and can save the patient an invasive procedure, reduce medical costs, and increase patient convenience. However, these anecdotal data have not been supported by studies.

In 1978 Dr. Stuart Stanton stated, "In order to make the correct diagnosis (of stress incontinence) the clinician must rely on a thorough history and clinical examination aided by shrewd selection of the appropriate investigations." However, Dr. Stanton was unable to delineate exactly which were the appropriate investigations to be performed. Several authors attempted to outline more clearly the appropriate history and procedures necessary to ensure the accuracy of the diagnosis of incontinence: In 1975 Farrar et al.[2] reported that 96.4% of patients with a history of stress incontinence had stable bladders by urodynamic evaluation but that 89% of those who complained of urge incontinence had evidence of unstable bladders. Later work did not support this. In 1980 Cardozo and Stanton[3] showed that only 38% of women with detrusor instability reported urge and that nearly half of the women who complained of stress incontinence had unstable bladders; this proves that the patient's history was highly unreliable as diagnostic information.

In 1982 Kauppilla et al.[4] reported a detrusor instability score that used multiple questions thought to be relevant to the diagnosis of detrusor instability. The higher the score, the more likely the presence of detrusor instability and the less likely that surgical treatment could correct the incontinence. Indeed, those authors were able to predict 90% of the successful surgical corrections.

In 1988 Sand et al.[5] found that only 86.9% of the patients who complained of stress incontinence had genuine stress incontinence, although 36.6% who complained of urge or urge incontinence had detrusor instability. In the same year Walters and Shields[6] used history and the physical finding of a moderate to large cystocele to achieve a 100% sensitivity for genuine stress incontinence. However, the specificity was only approximately 22%. However, this ruled out 96% of other urologic disorders.

In their article the authors considered many historic and objective criteria to determine their correlation with the ultimate diagnosis of urinary incontinence made by multichannel urodynamic testing. Indeed, the ability to correlate these commonly and easily performed outpatient test results and history questionnaires with urodynamic evaluation was only poorly to moderately successful. However, they put forth a number of questions that may help clarify that correlation and may make it more clinically useful.

In this study surgery to correct incontinence had been performed in 26 patients. What type of surgery was performed in these patients, and did the type of surgery correlate with the type of incontinence found later? As most will agree, patients with recurrent incontinence or with complex histories of incontinence deserve multichannel urodynamic evaluation. Is it appropriate to include these patients in this study, which is more applicable to primary incontinence? Although no statistical difference was found between the individual diagnosis and the patient's age, it is well recognized that older women more frequently have uncontrolled bladder contractions, the relevance of which is

unknown. Therefore was there a statistical correlation among the age of the patient, the presence of uncontrolled bladder contractions, and the diagnosis of a mixed disorder?

In the patients studied more than a week passed between the initial testing and subsequwnt multichannel urodynamic testing. Detrusor instability is known to be intermittent and is perhaps suppressed or provoked by the anxiety of the first test. How much time elapsed between the first testing and the subsequent full urodynamic evaluation, and do the authors think that this may be relevant to the poor predictive value for detrusor instability.

The authors place equal weight on all the tests and questions presented. Would a weighted scale or a logistic regression analysis be more appropriate in the development of a formula to predict the final urodynamic diagnosis? Also, there are no obvious internal controls in the questionnaire to ensure adequacy or reproducibility of the patients' responses to the questions. Would not such an internal control be more useful with historic data?

Finally, as a result of this early work, what is recommended as the appropriate preoperative evaluation for a physician in a clinical setting who has a patient presenting with symptoms consistent with stress incontinence and findings of anterior vaginal wall prolapse?

DR. SUSAN R. JOHNSON, Iowa City, Iowa. I think that this type of technology assessment is important. Several of the participants in the discussion mentioned cost, and I wonder if the authors have taken their data one step further and looked at a cost-benefit analysis that would compare the outcomes of those who undergo surgery and those who do not as a result of this 90% predictive ability?

This would involve, for example, comparing the cost of performing only simple tests in 100 women, which would result in 10 unnecessary operations versus the cost of performing multichannel testing in all 100 women, which would eliminate those 10 unnecessary operations by means of testing that is more sophisticated.

DR. JOHN O.L. DELANCEY, Ann Arbor, Michigan. I would like to raise a philosophic question. The underlying assumption of many laboratory evaluations of urinary incontinence is that the cystometrogram reliably detects detrusor instability. As Dr. Cornella mentioned, we have realized that this is not at all the case.

A physical examination can be used to evaluate stress urinary incontinence. The entire framework of determining whether a patient has mixed incontinence or detrusor instability tests on the accuracy of the cystometrogram in the detection of detrusor instability. I wonder whether we shouldn't examine the fundamental assumption that a cystometrogram is an accurate diagnostic test.

A diagnostic error can be made if a 10-minute cystometrogram is used to exclude the diagnosis of stress urinary incontinence in an intelligent woman who describes an episode of detrusor instability and who has a negative cystometrogram.

DR. MICKEY KARRAM, Cincinnati, Ohio. I just want to reemphasize the point that discussants are making about detrusor instability.

The most recent International Continence Society recommendations and definitions no longer use a cutoff of 15 cm H_2O to define detrusor instability. The current definition is any increase in true detrusor pressure that is believed not to result from bladder compliance. A significant number of patients will have symptomatic urgency and urge incontinence but will not have rises of 15 cm H_2O. I am wondering why the current and most recent definition was not used in this study.

The second point concerns the use of a cutoff level of 30 degrees to define a positive or negative Q-Tips cotton swab test. No data in the literature support this, and I think that it is much better to describe bladder neck mobility by simply stating the straining angle.

Finally, the patients who had had previous surgery and recurrent stress incontinence are a separate group because the clinician must define or identify their condition and must also determine the type of stress incontinence (anatomic or sphincteric). Could the authors comment on this?

DR. JOSEPH C. SCOTT, JR., Omaha, Nebraska. I am curious about the degree-of anatomic defects in this patient population. I know that the authors are probably limited as to the information they can present, but it would be helpful if they could comment on the severity of the anatomic defects in this group of patients.

DR. SUMMITT (Closing). I knew that this topic would generate a significant amount of discussion. Whether I am equal to my discussants or questioners will be seen at the end. I shall do my best.

I shall begin my closing discussion in the order of questions received. Let me first address the question of urethral pressure profilometry and specifically some of the inaccuracies that have been suggested. I hope that I emphasized that this is not a "definitive diagnostic method." With regard to Dr. Cornella's question about

two different, inaccurate methods, we are limited by the technology we have. We use the technology available to us within diagnostic limitations, and we compensate for some of the inaccuracies by the use of direct observations.

In our methods we considered the study by Richardson (see reference 16 of the article), which showed a telescoping effect of the urethra that caused false positivity in pressure equalization during the cough profile. We do attempt to eliminate the deviation in pressure that occurs with movement. However, that is not always consistently possible, and we realize the intrinsic problems with that technique.

There also are problems when the patient does not cough hard enough. The patient may actually have stress incontinence that is not identified with cough urethral pressure profilometry. We attempt to repeat cough profiles several times during the same testing period to compensate for this inaccuracy.

Now I will address the use of specific definitions in our study. Because primarily one investigator performed the testing, we used rigid definitions of stress incontinence both for office testing and in urodynamic testing to avoid bias. I realized from the beginning that this might be a problem in the article, but we avoided the biases that might have arisen by our knowledge of the patient from earlier testing.

With reference to the validity of the patient's history, there are few data that show a good correlation of history with the final diagnosis of incontinence. Patient history can often be misleading. I think that the history is valuable as a guide to the evaluation. What brings the patient to your office is her complaint of urinary incontinence. Use the patient's history as a guide to and a measure of the severity of incontinence.

Now I would like to address the discrepancy in the cystometric findings described (88.5% accuracy with single-channel cystometrics) as opposed to the cystometric results (55%) in an earlier study by Sand et al. at the same institution.

The earlier study was a review in which both supine and standing cystometry were examined. Our study was a prospective evaluation with a single examiner who performed standing cystometry according to specific definitions and who correlated the cystometric results with the final diagnoses for which one of the other investigators and I had performed the multichannel urodynamic studies. It is my feeling that our improved methods probably account for the discrepancy noted.

Finally, I want to say that I am not discouraging the use of office testing, but I think that it is important to remember that even when the patient's history and office testing are used to make diagnoses there is a 10% to 15% inaccuracy rate in treatment that is based on these preliminary test results. This has been well documented in the article by Walters and Shields. (Dr. Cornella's reference 6).

In answer to Dr. Mercer's questions about previous surgery, we did review the numbers of operations, which ranged from one to four. There was no statistical correlation between the numbers of previous operations and the final diagnoses of incontinence. We even considered the types of operations. The majority of our patients had simple anterior repairs; the second highest number were retropubic urethropexy (primarily Marshall-Marchetti-Krantz) procedures. There was no statistical association between the type of prior incontinence surgery and the final diagnosis.

We did consider the patient's age, although I did not include that in the article. There was no statistical correlation between age and the final diagnosis.

Are contractions clinically relevant in the group with mixed incontinence? I think so. There is no consensus about treating patients with mixed incontinence, although most recommendations concern treating detrusor instability first. If involuntary contractions improve, the need for surgery can be reassessed. Treating detrusor instability may relieve the patient's incontinence so that she may desire no further therapy. In reference to Dr. Mercer's question about multivariant analysis, we did not use that method specifically. That has been done by Fischer-Rasmussen et al. (see reference 6 of article), who found no statistical correlation between that method and the final diagnosis.

In answer to the question of what to do for those patients for whom urodynamic testing is not available, I still think that according to our data, the patient's history is initially valuable in guiding the evaluation because it delineates the patient's problems and their severity. In the next step, which is clinical office testing, the Q-Tips cotton swab test has been valuable, not as a diagnostic tool but as a prognostic factor for surgery in certain patients. Several studies in the last 5 years showed that patients who have minimal mobility of the urethra and who also have stress incontinence may be at greater risk for failure with standard surgery to correct incontinence. That may partially address Dr. Karram's questions. I recommend that cystometrography be performed in addition to a cough stress test. The American College of Obstetricians and Gynecologists quality assurance criteria for performing surgery in patients recommend that a cystometrogram be obtained and that objective demonstration of urine loss be seen. This battery of tests should be the minimum evaluation when urodynamic testing is unavailable.

Now I would like to address the last questions. Dr. Johnson asked about the cost-benefit analysis. We have not examined this. Around the country, costs for multichannel urodynamic testing range from $200 to $400. Office testing costs can range up to $150 for a cystometrogram. I have not compared these tests, but that would be an interesting analysis.

With respect to Dr. DeLancey's questions about the cystometrogram, I think that most clinicians who perform urodynamic testing realize the minimal inaccuracies of cystometry. We realize that what may occur during 24 hours in a patient's life may not occur during a 10-minute test in the office. Sand et al. examined

simple office cystometry and suggested that repetitive testing on several occasions may result in a diagnosis of detrusor instability. We are considering that in further investigations.

With regard to Dr. Karram's question about the new definition of detrusor instability, we began this study in 1987, and we used the current definition at that time. As I said, we tried to maintain specific definitions throughout the study period to avoid bias in patient evaluation.

As far as the 30-degree cutoff for the Q-Tips cotton swab test, we tried to maintain specific definitions. In our data analysis we did not feel as if we could accurately use various measures of angle deviation in the Q-Tips cotton swab test. We maintained the 30-degree definition for ease of data analysis.

In answer to Dr. Scott's question about the degree of anatomic defects, we again made specific cutoffs, which may be a problem in the article with respect to the analysis of the patient population. The nature of our patient population may have skewed the anatomic findings. The majority of our patients did not have severe cystoceles or significant Q-Tips cotton swab test deviations.

Mechanism of recurrent spontaneous abortion

I. Ultrasonographic findings

J. Jaroslav Stern, MD, and Carolyn B. Coulam, MD
Indianapolis, Indiana

OBJECTIVES: Our objective was to study the mechanisms of early pregnancy loss with ultrasonographic findings in pregnancies that terminated in repeat abortion in women with recurrent spontaneous abortion compared with patients with spontaneous abortion with no previous spontaneous abortion and with women with recurrent spontaneous abortion who had viable pregnancies.
STUDY DESIGN: A prospective, unselected study of 83 pregnancies followed from 4 to 12 weeks of gestation. Weekly transvaginal ultrasonography among 43 pregnancies terminating in abortion were compared with 40 pregnancies ending in live birth with the Fisher exact test with a p value of significance assigned at <0.05.
RESULT: A significant difference in the presence of fetal heart activity was observed at 6 weeks ± 5 days among women who subsequently aborted when recurrent spontaneous abortions were compared with no history of abortion (55% and 14%, $p < 0.02$). Fetal pole size was small in 86% of pregnancies lost after fetal heart activity.
CONCLUSION: Ultrasonographic examination at 6 weeks can diagnose impending abortion with a sensitivity of 85%, specificity of 93%, positive predictive value of 92%, and negative predictive value of 87% among women with recurrent spontaneous abortion. (Am J Obstet Gynecol 1992;166:1844-52.)

Key words: Recurrent spontaneous abortion, ultrasonography

The inability of a couple to achieve desired family size affects an estimated three million couples in the United States.[1] Reproductive life-table analysis indicates that the majority of reproductive failures results from postfertilization failures occurring before or after implantation.[2] Childlessness as a consequence of repeated postimplantation losses has been described as a syndrome[3] termed recurrent spontaneous abortion. Although the syndrome has been defined as three or more consecutive spontaneous abortions,[3] a number of studies include those with two consecutive spontaneous abortions. Rationale for including women with two spontaneous abortions is provided by the observations that the greatest change in risk of losing a subsequent pregnancy comes after two consecutive abortions,[4] and no differences in the prevalence of etiologic factors exist between couples with three or more abortions.[5]

ASA, Recurrent spontaneous abortion; *Non Ab,* no history of abortion.

Recurrent spontaneous abortion occurs in 2% to 5% of reproductive aged women each year.[4, 6] The etiologies have been reported as being due to anatomic, hormonal, chromosomal, and immunologic causes.[7] Although recent reports suggest that immunologic causes account for a number of heretofore unexplained cases,[8-11] the mechanisms of fetal loss are not known. To study the mechanisms of early pregnancy loss, 83 pregnancies were monitored ultrasonographically during the first 12 weeks of gestation. This report describes the ultrasonographic findings of pregnancies occurring in women with recurrent spontaneous abortion that terminated in repeat abortion and compares these findings with those of spontaneous abortions occurring in women with no previous spontaneous abortions and in women with recurrent spontaneous abortion who had viable pregnancies.

Material and methods

Pregnancies. A total of 83 pregnancies were studied (January 1990 to December 1990) from week 4 to week 12 of gestation. Of these 83 pregnancies, 43 terminated in first trimester spontaneous abortions and 40 produced live births. A previous history of recurrent spontaneous abortion was present in 69 pregnancies, and 14 pregnancies occurred in women with no previous abortions. Among the 69 pregnancies occurring in women with a history of recurrent spontaneous abortion, 40 resulted in a viable birth and 29 ended in repeat abortion. An abnormal chromosome analysis was documented in seven of the products of conception from first trimester spontaneous abortions.

Ultrasonographic monitoring. Eighty-three pregnancies were followed during the first 12 weeks of gestation with an ATL Ultramark ultrasonography machine with a 5 MHz transvaginal probe (Advanced Technology Laboratories, Bothell, Wash.). At the time of each examination the gestational sac and yolk sac were measured in three diameters, and these measurements were averaged and recorded. The length of the fetal pole was measured and recorded. The presence or absence of fetal heart activity was noted. The size and rate of growth of the gestational sac and fetal pole were compared with those expected from the last menstrual period (LMP), as determined by the method of Hellman et al.[12] and Silva et al.[13]

Progesterone and human chorionic gonadotropin determinations. At the time of each ultrasonographic examination, blood was drawn from the antecubital vein of each woman for determination of progesterone and human chorionic gonadotropin (hCG). These levels were determined by radioimmunoassay (Diagnostic Products, Los Angeles). Statistical analysis was performed with Fisher's exact test with a p value of significance assigned at <0.05.

Results

The overall ultrasonographic findings during the first trimester observed in 83 pregnancies are summarized in Table I. All 40 pregnancies producing a live birth demonstrated a gestational sac containing a fetal pole with fetal heart beat visualized on real time. Among the 43 pregnancies terminating in abortion, 16% displayed no gestational sac, 28% revealed a gestational sac with no discernible fetal pole, 7% had a fetal pole with no observable heartbeat, and 49% demonstrated the presence of fetal heartbeat. No differences in the frequencies ultrasonographic findings were observed when pregnancies in women with a history of recurrent spontaneous abortion were compared with no history of previous abortion. In addition, no differences in the frequency of the presence or size of the yolk sac were seen when pregnancies in women with a history of recurrent spontaneous abortion were compared with a history of no previous abortion.

Seven of the abortuses displayed an abnormal chromosome analysis. Two chromosome abnormalities were found in patients with history of recurrent spontaneous abortion (47,XX +15, 48,XX +13 +16) and five in those patients with no prior abortion (69,XX, 47,XX +22, 45,X, 47,XX +22, 69,XXX). The abnormal karyotypes observed are listed in Table II and the ul-

Fetal heart activity	6	86

trasonographic findings in these pregnancies are shown in Table III. All pregnancies demonstrating an abnormal karyotype had a fetal pole visible on ultrasonographic examination, and all but one displayed the presence of fetal heart activity.

The frequency of ultrasonographic findings at specific weeks of gestation during the first trimester among women with a history of recurrent spontaneous abortion are shown in Table IV. All pregnancies revealing no gestational sacs were diagnosed by 6 weeks of gestation. Also by 6 weeks of gestation 95% of all pregnancies producing a live birth demonstrated the presence of fetal heart activity. Table V summarizes the findings of a single ultrasonographic examination performed at 6 weeks ± 5 days in successful and unsuccessful pregnancies among women with a history of recurrent spontaneous abortion and no history of previous abortion. A significant difference in the frequency of finding the presence of fetal heart activity was observed in pregnancies producing a live birth compared with pregnancies ending in abortion ($p < 0.00001$) and in those pregnancies terminating in abortion when women with a history of recurrent spontaneous abortion were compared with women with no previous history of abortion ($p < 0.01$). Among 29 pregnancies terminating in abortion in women with a history of recurrent spontaneous abortion, 16 (55%) demonstrated the presence of fetal heart activity on an ultrasonographic scan performed at 6 weeks' gestation. By contrast, two of 14 (14%) of pregnancies terminating in abortion among women with no previous abortion displayed fetal heart activity at 6 weeks of gestation.

Table VI describes the size of the fetal pole compared with the expected size on the basis of the LMP among those pregnancies demonstrating fetal heart activity at 6 weeks' gestation. The majority (86%) of pregnancies that aborted after the establishment of fetal heart activity had fetal poles that were <0.6 week from expected size on the basis of the LMP. By contrast, only 10% of pregnancies ending in live birth had fetal poles measuring <0.6 weeks from expected size at 6 weeks' of gestation. Serum progesterone and hCG concentrations were not low among those pregnancies terminating in abortion after demonstration of fetal heart activity at 6 weeks (Table VII).

Serum progesterone and hCG concentrations in pregnancies from weeks 4 through 12 of gestation among 69 women with a history of recurrent spontaneous abortion are summarized in Tables VII and VIII. No differences in progesterone or hCG concentrations were observed when these values were compared among women aborting their pregnancies and those producing a live birth. Table IX describes those pregnancies in which serum progesterone concentrations drawn at 6 weeks' gestation were <10 ng/ml. Fourteen of the 83 pregnancies (17%) studied produced serum concentrations of progesterone concentrations of <10 ng/ml at 6 weeks' gestation; nine of these 14 pregnancies (64%) occurred in women who subsequently aborted and five (36%) were observed in women who delivered a live birth. Pregnancies terminating in abortion had progesterone levels of <10 ng/ml at 6 weeks 21% of the time. When those 14 pregnancies with low progesterone concentrations at 6 weeks were correlated with ultrasonographic findings at the same period of gestation, a difference between pregnancies ending in live birth and abortion was seen (Table X). All pregnancies associated with progesterone concentrations of <10 ng/ml that subsequently ended in live birth had fetal heart activity on ultrasonographic examination at 6 weeks, and 80% of these demonstrated sizes of fetal poles consistent with expected dates. In contrast, one of the nine pregnancies (11%) with low progesterone values that subsequently terminated in abortion had fetal heart activity documented on ultrasonographic examination. This one pregnancy had a fetal pole smaller than expected size. The remaining 89% of pregnancies with low progesterone concentrations displayed an empty sac or a small fetal pole with no demonstrable cardiac activity at the time the low progesterone values were observed.

Comment

The ultrasonographic observations in this study help to describe mechanisms involved in spontaneous abortion. No gestational sac was observed in 16% of preg-

nancies terminating in abortion, empty gestational sac in 28%, and fetal pole with absence of fetal heart activity in 7%. In 49% of spontaneous abortions, the pregnancy was lost after demonstration of fetal heart activity. The frequencies of these ultrasonographic findings were significantly different when abortions in women with a history of recurrent spontaneous abortion were compared with those in women with a history of no previous abortions at 6 weeks' gestation. Fifty-five percent of women with a history of recurrent spontaneous abortion aborted after documentation of fetal heart activity at 6 weeks, whereas 14% of women with no history of previous abortion demonstrated the presence of fetal heart activity at 6 weeks' gestation.

Among all pregnancies that aborted after demonstration of fetal heart activity, the ultrasonographic date of the pregnancy determined by measurement of the fetal pole was <0.6 week from expected dates on the basis of the LMP in 86%, suggesting that blood flow to the embryo was diminished. Immunohistochemical findings from placentas of first-trimester spontaneous abortions support this view in that 50% of conceptuses that were aborted have evidence of an increase in immunopathology.[14] This lesion is associated with activated endothelial cells of fetal stem vessels. Thrombomodulin disappears from plasma membranes of activated endothelial cells and tissue factor appears.[15] Tissue factor activates factor VII of the extrinsic coagulation pathway, leading to fibrin deposition and platelet-fibrin thrombi.[16] Thus the fetal stem vessel endothelial surface is changed from a thromboresistant surface to a thrombogenic surface, and blood flow to the growing conceptus is diminished. Khong et al.[17] described changes in spiral arteries in placental beds from abortuses. The physiologic changes occurring in the spiral arteries from weeks 6 through 12 of gestation that result in increased blood flow through the uteroplacental arteries and into the intervillous space were absent.[18] Physiologic changes are the result of migration of extravillous trophoblasts from the cytotrophoblastic shell and tips of anchoring villi into decidua basalis and subsequent myometrium and migration of endovascular trophoblasts retrogradely into the walls of spi-

ral arteries. The muscular and elastic tissue in the arterial wall are replaced by a fibrinoid material converting them into flaccid distended tubes, allowing a tenfold increase in blood flow. Any event that would diminish blood flow to the fetus through spiral arteries or fetal stem vessels would result in fetal starvation. The ultrasonographic observations of pregnancy loss after establishment of fetal heart activity of smaller-than-expected fetal poles would suggest a problem in fetal blood flow. Because physiologic changes in the spiral artery do not occur until 6 weeks of gestation and because the fetal pole is already smaller than the expected size by 6 weeks of gestation, the compromise in fetal blood flow most likely occurs within the fetal stem vessels. Evidence of fetal starvation before abortion occurs in 88% of pregnancies from women with a history of recurrent spontaneous abortion.

That the mechanism of abortion after the establishment of fetal heart activity is related to deficiencies in fetal blood flow rather than abnormal trophoblastic cell function is suggested by the lack of difference in serum progesterone and hCG concentrations in women who abort compared with those who produce a live birth (Tables VII and VIII). Further support for the concept that trophoblastic dysfunction is an effect rather than a cause of abortion is gained from the observation that 89% of pregnancies associated with low progesterone concentrations displayed the absence of fetal heart activity at the time the low progesterone values were obtained.

Whatever the mechanism of the abortion, a single ultrasonographic examination at 6 weeks of gestation can be used to predict pregnancy outcome. Among pregnancies that abort, 58% have absent fetal heart activity at 6 weeks (empty sac or fetal pole without fetal heart activity) (Table V). Of the 42% of pregnancies

Fetal pole <0.6 wk	1	20	1	17	0	0

that abort after demonstration of fetal heart activity, 86% are <0.6 week than expected age on the basis of the LMP (Table VI). Only three of 43 pregnancies (8%) that aborted were not predicted at the time of the 6-week ultrasonographic examination. Thus, on the basis of the finding of presence or absence of fetal heart activity and the size of the fetal pole, 92% of spontaneous abortions can be predicted by evaluating a single ultrasonographic examination at 6 weeks' gestation.

Fig. 1 outlines how a single ultrasonographic examination at 6 weeks' gestation can be used clinically. Of 83 pregnancies examined 27 (33%) had an absence of fetal heart activity, and 25 (93%) of these pregnancies were lost. The presence of fetal heart activity in a fetal pole measuring <0.6 week from LMP occurred in 19 pregnancies. Fifteen of these pregnancies (79%) terminated in abortion. Of 37 pregnancies displaying the presence of fetal heart activity and fetal size not <0.6 week from LMP, three (8%) aborted. Thus in diagnosing impending abortion a single ultrasonographic examination at 6 weeks had a sensitivity of 85%, a specificity of 93%, a positive predictive value of 92%, and a negative predictive value of 87%. These values can also be calculated for women with a history of recurrent spontaneous abortion (Fig. 2). Of the 69 pregnancies occurring in women with recurrent spontaneous abortion, 29 ended in repeat abortion and 40 produced viable births. Ultrasonographic examination of these 69 pregnancies at 6 weeks' gestation revealed the absence of fetal heart activity in 15 (22%) and the presence of fetal heart activity in a fetal pole measuring <0.6 week from LMP in 18 (33%). Repeat abortion occurred in 13 of the 15 (87%) pregnancies with absent fetal heart activity and in 14 of the 18 pregnancies (78%) with fetal heart activity in fetal poles measuring <0.6 week from LMP. Thus in diagnosing a repeat abortion in women experiencing recurrent spontaneous abortion, a single ultrasonographic examination at 6 weeks' gestation had a sensitivity of 85%, a specificity of 93%, a positive predictive value of 94%, and a negative predictive value of 81%.

We conclude that ultrasonographic findings describing mechanisms of abortion are different when pregnancy losses experienced by women with a history of recurrent spontaneous abortion are compared with those with a history of no previous abortion. In addition, a single ultrasonographic examination at 6 weeks is predictive of spontaneous abortion in 92% of pregnancy losses. It is hoped that the information gained from these studies will lead to efficacious treatment and to better diagnosis of recurrent spontaneous abortion.

Discussion

DR. LEEBER COHEN, Chicago, Illinois. This article compares a small group of 14 previously nonaborting women who aborted with a larger group of 69 patients with a history of recurrent spontaneous abortion. It was designed to test the hypothesis that early embryogenesis as evidenced by vaginal ultrasonography will differ between these groups. This study is important because it could help identify women who are at higher risk of

recurrent abortion. Presumably evaluation for immune causes of recurrent abortion could then be evaluated and therapy initiated.

The authors have two major findings. The first is that fetal heart activity is present more frequently (55% vs 14%, $p < 0.02$) at 6 weeks' gestation in women with recurrent spontaneous abortion with another recurrent abortion than in a group of previously nonaborting women who abort. Second, they observe that fetuses with demonstrated heart tones that subsequently abort have significantly smaller crown-rump lengths than expected 86% of the time.

Because the authors are using two or more consecutive spontaneous abortions as a definition for recurrent spontaneous abortion, it might be useful to provide the risk rates for consecutive abortion after one, two, and three losses from the literature.

The Material and Methods section doesn't give information on age, reproductive history, or treatment for infertility or reproductive loss. The control group of previously nonaborting women with abortions is quite small. In addition it is not clear where these patients were recruited. To be able to extend any conclusions to the general population the control group should include a subgroup of nonaborters with successful pregnancies. To elaborate on this point, the data presented reveal that 29 of 69 (42%) of the recurrent spontaneous abortion patients had repeat abortions. We cannot calculate the abortion rate in the previously nonaborting group.

The authors need to clarify why in Table I seven of 14 previously nonaborting aborters had fetal heart activity at some time during the first trimester, but only two of 14 of the same group had fetal heart activity at 6 weeks in Table V. Did the other five fetuses have delayed appearance of the fetal heart activity and subsequently abort? Table II could be eliminated and discussed in the text. Table III could be eliminated and would make an interesting topic for another article with larger numbers. Table IV should be expanded to include a group of previously nonaborting women and correlate the ultrasonographic findings among subsequent aborted and live birth pregnancies. Table V lacks a column for viable births after no history of abortion. Table VI should be revised. Figs. 1 and 2 should be revised. The mean, median, and standard deviation measurements for normal pregnancies should be provided. The percentages of pregnancies aborting then could be graphically demonstrated. A similar figure for recurrent spontaneous abortion pregnancies could follow. The data in Tables VII through X should be placed in a second article. A brief statement as to the findings could be referenced.

Overall, the authors have made a potentially interesting observation. Specifically, they describe an ultrasonographic finding of a small-for-gestational age crown-rump measurement in a fetus with fetal heart activity at 6 weeks that subsequently aborted. The authors' findings suggest that this may be due to immune factors.

The findings that fetuses with small-for-gestational-age crown-rump lengths are at risk for spontaneous abortion are supported by a recent article by Nazari et al.[1] The authors might discuss the finding of Bromley et al.[2] that small-for-dates sac size is associated with spontaneous abortion. Similarly, they might discuss the report that abnormalities of fetal heart activity rates in the early fetus have been associated with abortion.[3]

Dr. Tariq Siddiqi, Cincinnati, Ohio. The stated purpose of this investigation by Drs. Stern and Coulam was to "study the mechanisms of early pregnancy loss." Although an interesting and somewhat unique investigation, the conclusions drawn from this study are open to question. The investigators do not define whether this was a prospective or a retrospective study, i.e., how was the study population selected? Are these 83 consecutive patients of whom 69 happened to be recurrent aborters? If so, then a 100% abortion rate in patients with no history of abortion appears excessive. What were the inclusion or exclusion criteria? Were the patients who had live births relatively similar to those who aborted in regard to maternal characteristics such as age, gravidity, parity, and medical or surgical complications? If not, then we may be at risk of comparing apples and oranges.

The authors also do not define whether all patients were serially studied from 4 to 12 weeks of gestation, i.e., is this a longitudinal or a cross-sectional study? Ultrasonographic instruments, even transvaginal transducers, have inherent limitations such that a frequency of 7 MHz, the average lateral resolution is 1.3 mm. To this we may add the average standard deviation of 1.2 mm of three crown-rump length readings as stated by Robinson[1] in his original article analyzing the accuracy of crown-rump length measurements. Also, Robinson himself[2] was concerned about the reliability of measurements <12 mm, i.e., at <7 weeks gestation. The authors do not provide any information regarding their actual crown-rump length measurements nor do they make a distinction between observer and observation differences. This information is critical to evaluate their data, because a single measurement at 6 weeks' gestation will be in a range <10 mm, and on the basis of published data subject to a measurement error of ±2.5 mm. The data would be more meaningful when compared as the mean ± SD crown-rump length measurements in the live birth versus the abortion groups. It is therefore difficult to understand why the investiga-

tors chose to present their data as "weeks' gestation" rather than as actual crown-rump length measurements in millimeters. In fact, Robinson's ability to predict gestation is subject to a limitation of ±4.7 days, and 0.6 weeks falls within this error range. Finally, there are no statistical methods described in the manuscript.

As clinicians, we know LMPs are often inaccurate, yet these are used as a gold standard for estimating gestational age in this study, with ultrasonographic measurements being the dependent variable. How reliable are the LMPs in the study patients or are fertilization dates known to the investigators? In my opinion, the ultrasonographic observations are completely unrelated to the authors' hypothesis of fetal starvation as the mechanism underlying spontaneous abortion. They have neither performed biopsies of the implantation sites nor evaluated blood flow ultrasonographically to even speculate that blood flow is diminished in cases of spontaneous abortion. In fact, seven of the abortuses had an abnormal chromosone analysis, suggesting mechanisms other than diminished blood flow. Finally, are the authors really suggesting that in the event of a slightly smaller-than-expected crown-rump length measurement at 6 weeks' gestation and in light of known technical limitations spontaneous abortion is almost inevitable?

Dr. Stern (Closing). This was a prospective unselected study. These patients were seen at the clinical office of the center from Jan. 1 to Dec. 31, 1990; we performed a retrospective analysis on the basis of pregnancy outcome. The mean age of the patients was 32 years, and the mean gravidity was 3.6. The pregnancies were followed starting on the fourth week of gestation until the end of the first trimester. All the pregnancies were studied with a transvaginal ultrasonography and blood test every week.

The results were reported by gestational age because this parameter is the most commonly use in clinical practice. The mean length of the normal fetal pole at 6 weeks was of 5 mm, with a range between 2 and 8 mm. Fisher's exact test was used for the statistical analysis.

The purpose of this study was to offer the clinician a tool to predict fetal outcome. We agree that knowing the exact time of conception will allow a more specific test. The problem is that in the clinical setting, the patient does not know the date of conception.

We grouped the patients with chromosomal abnormalities in one group trying to observe a difference in the ultrasonographic findings. We did not see a difference.

Our hypothesis is that recurrent spontaneous abortions have an immunologic component that activates the coagulation system, clotting the vasculature of the placenta; this will produce inadequacy in the growth of the fetus, giving a small fetus.

Acute childbirth morbidity: Its measurement using hospital charges

Marvin L. Hage, MD,[a] Michael J. Helms, BS,[b] Adams Dudley, MBA,[c] William W. Stead, MD,[d] William E. Hammond, PhD,[b] Catherine Neyland, MHA,[c] and Charles B. Hammond, MD[a]

Durham, North Carolina

OBJECTIVES: An analytic descriptive analysis of acute childbirth morbidity was carried out at Duke University Medical Center, comparing patients delivered by primary cesarean section with those delivered vaginally.

STUDY DESIGN: All primary cesarean deliveries and vaginal deliveries from July 1, 1981, through June 30, 1986, were combined with maternal and infant charge data. A total of 7256 patients were analyzed. A description of the charges for the associated diagnoses was carried out. A morbidity index was used to identify differences in predicted median hospital charges with 95% confidence intervals.

RESULTS: The ratio of mean primary cesarean delivery to mean vaginal delivery total charges was 2.5:1. The magnitude of the mean hospital charges was inversely related to the frequency of the indication with the lowest charges associated with dystocia and the highest with multiple pregnancy. Antepartum risk factors (increased maternal age, patient referral) were associated with increases in maternal and infant morbidity as measured by the morbidity index. Chronic maternal hypertension resulted in decreased maternal morbidity but increased infant morbidity when primary cesarean delivery was used. Although preterm delivery was associated with large increases in charges, it was not significantly altered by using primary cesarean delivery. Risk factors associated with the management of abnormalities of labor were associated with deceases in maternal and infant morbidity when primary cesarean delivery was used.

CONCLUSION: Analysis of acute childbirth morbidity, as measured by hospital charges, showed marked variation of diagnosis and risk-specific charges for patients delivered by primary cesarean section. (Am J Obstet Gynecol 1992;166:1853-62.)

Key words: Childbirth, morbidity, cesarean, measurement

In the conclusion of the book *Costs, Risks, and Benefits of Surgery*,[1] the authors' first recommendation is that "Appropriate studies of the effectiveness of surgical treatment should be carried out for selected conditions, particularly those where uncertainty leads to professional disagreement." In spite of this recommendation, limited information exists regarding the costs of cesarean delivery.[2-8] This study describes childbirth morbidity at Duke University Hospital by a retrospective comparative analysis of maternal and infant hospital charges for primary cesarean and vaginal deliveries. The rationale for this approach hinges on the use of appropriate statistical methods that can characterize this outcome measure.

Methods

A perinatal outcome evaluation measurement should be a reliable, objective index that can be ascertained in the perinatal period, which relates to future health and well-being.[9] Hospital charges would appear to be such an index of acute morbidity severity in that it is an objective measure that can be determined in the perinatal period. This study explores the use of hospital charge data in a 5-year analysis from July 1, 1981, to June 30, 1986, comparing vaginal delivery to primary cesarean delivery. As described in other clinical economic studies,[10] a comprehensive summary of costs or charges is not intended.

In a previously published paper,[11] the obstetric profile of patients cared for at Duke University Medical Center was described. Determinants of the prevalence of primary cesarean delivery were described as either major diagnostic categories or as risk factors. The hospital information system archives from July 1, 1981, to June 30, 1986, for both infants and mothers were searched for the hospital charge data and matched to the existing data set of clinical information with hospital identification codes for the mother and the date of delivery.

Because the hospital charge data did not meet normal distribution requirements, transformations of the data were explored in an attempt to satisfy normality requirements of the general linear models statistical procedures. These transformations proved difficult. A nonparametric method, analysis of the ranks of the charges, was next used to describe differences between groups. A distribution-based analysis was finally used, a proportional hazards model assuming a Weibull distribution of hospital charges. This seemed to fit the distribution of the hospital charges. Model testing was carried out in a random sample of the data and com-

pared with the remaining data. Predicted median hospital charges with their 95% confidence intervals for selected antepartum and intrapartum risk factors were used to compare the effects of the method of delivery and the risk status for selected antepartum and intrapartum risk factors. The data were analyzed with the Statistical Analysis System release 5.18 and 6.03 (SAS Institute, Inc., Cary, N.C.).

Results

Table I describes the sample of primary cesarean and vaginal deliveries in the study sample by year. This sample captured 89.1% of vaginal and primary cesarean deliveries for the period of study. A higher ascertainment would have been more likely if an account code would have been present in both data sets. The distributions of maternal and infant charges are displayed in Figs. 1A and 1B. Distributions of charges by route of delivery for both maternal and infant charges are highly skewed to the right. Mean hospital charges for each year, type of delivery, and for both mother and infant are displayed in Fig. 2. Charges seemed stable for vaginal deliveries and for maternal charges for cesarean deliveries. Larger variations occurred in the infant charges for cesarean deliveries. No linear secular trends are observed. The ratio of mean primary cesarean to mean vaginal delivery charges was 2.5:1.

These predicted median charges were calculated with the SAS procedure Lifereg with the Weibull distribution for hospital charges. *NS*, Not significant.

*Significant reduction in charges within a given method of delivery.

Fig. 3 illustrates the distribution of mean charges by major diagnosis with the frequency of occurrence of the diagnostic categories for primary cesarean delivery. Total charges are inversely related to the frequency of occurrence for these diagnoses, with the highest charges for multiple pregnancy and the lowest charges associated with dystocia. Most of the variation was related to infant charges.

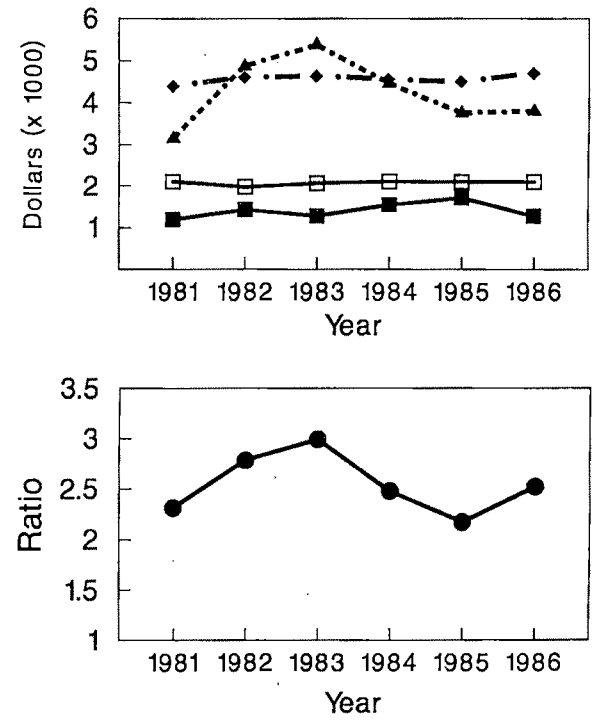

Fig. 2. Mean hospital charges and ratio of cesarean/vaginal charges. During study period, no overall trend is demonstrated for mean hospital charges for either infants or mothers. Variation in charges is specifically related to changes in charges of infants delivered by cesarean section.

Table II lists the predicated median hospital charges for the fitted model and their 95% confidence intervals for selected risk factors that had previously been identified as significantly affecting primary cesarean delivery rates. The effect of the risk factor and the method of delivery usually significantly increases charges, with more profound effects for infant charges. Notable exceptions, no significant difference, were observed for maternal vaginal delivery charges for nulliparous women, prolonged latent phase of labor, and late decelerations. Also, no significant differences were observed for maternal primary cesarean charges for chronic hypertension, prolonged latent phase of labor, and oxytocin induction. A significant reduction in predicted maternal charges was noted for primary cesarean delivery with nulliparous women and late decelerations.

Changes in predicted infant charges again showed significant increases with the risk factors, except for vaginal delivery infant charges for nulliparity and maternal age ≥30 years and late decelerations. Preterm delivery was associated with large increases in infant

charges, in spite of the method of delivery. Primary cesarean delivery infant morbidity was not significantly altered by a maternal age ≥30 years. Significant reductions in infant charges for primary cesarean delivery was noted for the risk factors of nulliparity, prolonged latent phase of labor, late decelerations, and oxytocin induction.

Fig. 4 summarizes the change in maternal morbidity for selected antepartum and intrapartum risk factors as a function of the method of delivery, i.e., primary cesarean versus vaginal delivery. The percent change was calculated as the ratio of the fitted predicted median charges of cesarean delivery to vaginal delivery with and without the risk factor. Maternal or infant indices that were close to unity were interpreted as showing no change in morbidity, those greater than unity as showing increased morbidity with primary cesarean delivery, and those less than unity as showing reduced morbidity with primary cesarean delivery. Fig. 5 summarizes the change in infant morbidity for the same factors as a function of the method of delivery.

The morbidity, as measured by hospital charges, shows both increases and decreases in morbidity with the use of primary cesarean delivery, with larger overall effects on infant morbidity. Mothers ≥30 years old and referral patients demonstrated increases in maternal and infant morbidity, whereas patients with intrapartum abnormalities (late decelerations, prolonged latent phase of labor, and oxytocin induction) were associated with decreases in maternal and fetal morbidity. Nulliparity was associated with decreases in maternal and infant morbidity. Preterm deliveries with primary cesarean delivery did not significantly change relative infant morbidity and only slightly reduced maternal morbidity. In contrast, primary cesarean delivery for patients with chronic hypertension significantly reduced maternal morbidity but increased infant morbidity.

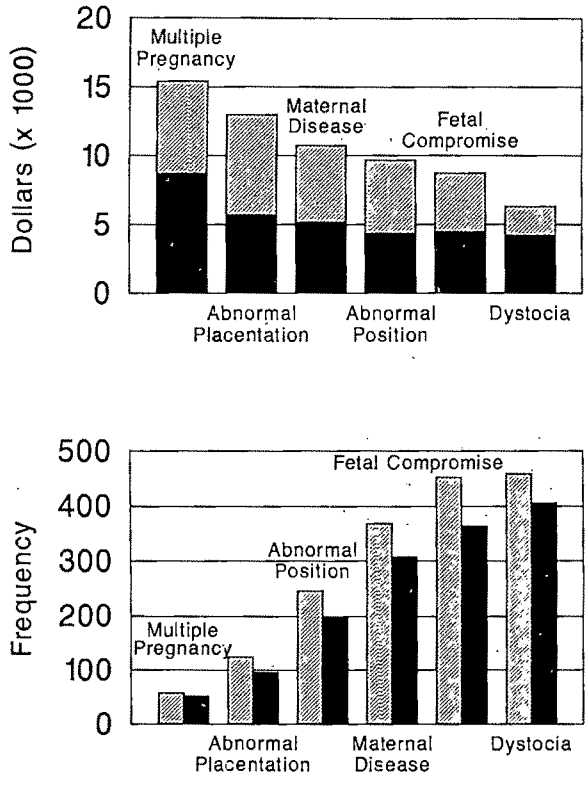

Fig. 3. Major diagnostic categories of primary cesarean delivery. Mean hospital charges and frequency of occurrence. The inverse relationship of total hospital charge to frequency of occurrence of major diagnostic category is demonstrated. *Solid bar,* Maternal; *hatched bar,* infant.

Comment

Two issues are explored in this study: (1) the use of hospital charges as a measure of acute childbirth morbidity, and (2) the hospital charges associated with primary cesarean and vaginal deliveries at Duke University over a 5-year period.

Hospital charges as a measure of acute childbirth morbidity. Childbirth morbidity can be defined as a continuum of outcomes that require the use of increased resources to restore the mother and infant to a normal state of health. It has been time limited to those events that affect the health of the mother or infant from the onset of labor to 6 weeks post partum. Consequently, the key to the measurement of morbidity is to find some measure that represents the use of resources around the time of childbirth.

The use of economic parameters to measure the effects of diagnostic variables on clinical outcomes has been infrequent. Charges have been seen as a measure of process and so poorly standardized they precluded comparisons within or between groups. In this study the temporal stability of hospital charges fulfilled an important criterion for any measure of outcome validity, relative secular stability.

The statistical analysis of any economic outcome is limited by the distribution of this measurement and the type of analysis performed. Three types of analyses are described in the literature,[9] cost-benefit, cost-effectiveness, and cost identification. Each has a slightly different purpose. Cost identification seems to apply to this study of childbirth outcomes in that it enumerates the charges in the provision of this service. The statistical methods have usually used mean costs or mean charges with data that, as shown in this paper, is highly skewed. The identification of a parametric model with the proportional hazards approach has not appeared in the literature. This approach offers the advantage of being able to model the effects.

A population-based approach seems poossible in that most of the population giving birth in the United States

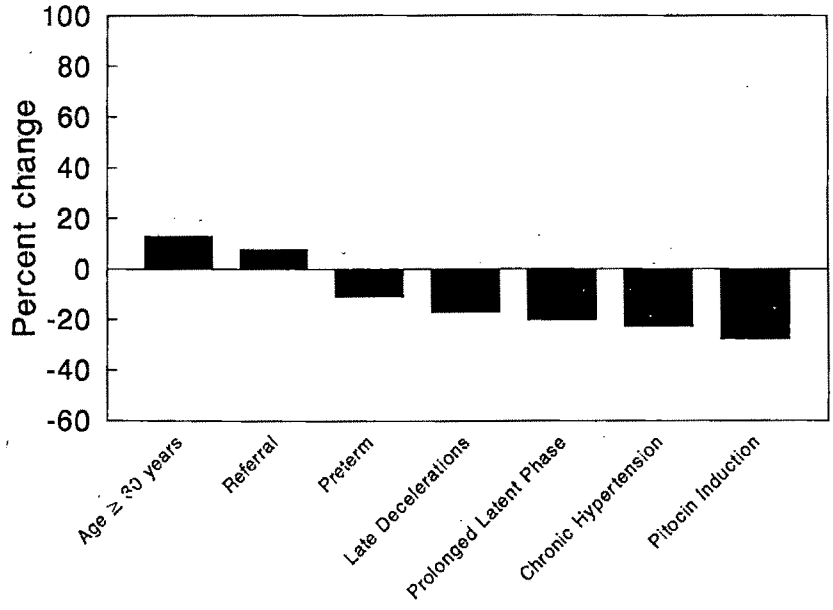

Fig. 4. Change in morbidity for mothers with use of primary cesarean delivery. Percent change was calculated from predicted median charges for both mothers and infants for each risk factor.

$$\text{Percent change} = \frac{\text{Predicted median (cesarean) with risk present/ Predicted median (cesarean) with risk absent}}{\text{Predicted median (vaginal) with risk present/ Predicted median (vaginal) with risk absent}} - 1 \times 100$$

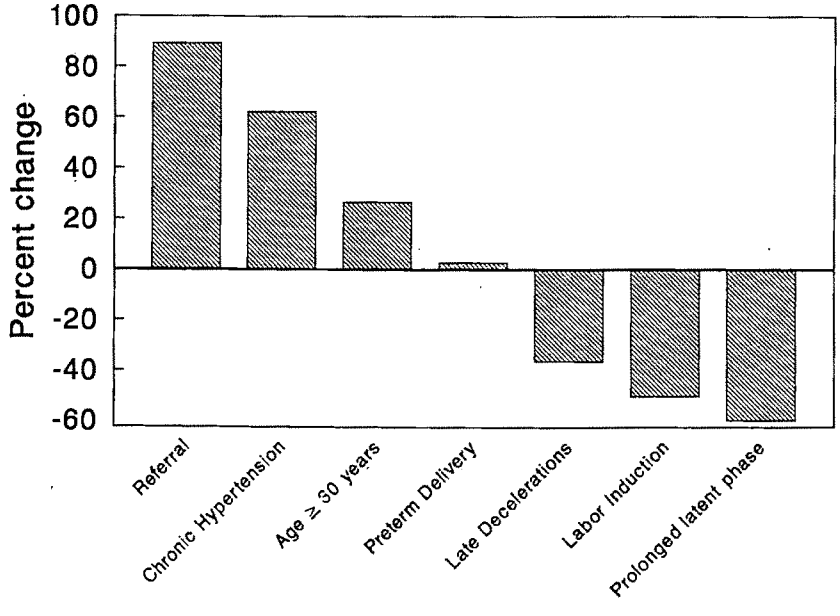

Fig. 5. Change in morbidity for infants with use of primary cesarean delivery.

does so within a hospital environment with known hospital charges. If used on a national level, standardization to national indexes could be used in comparisons between different geographic areas.

Childbirth morbidity of primary cesarean and vaginal delivery. The clinical question is the comparative question of the morbidity of cesarean versus vaginal delivery in risk-specific or disease-specific groups. Apgar scores, length of hospital stay, days on a ventilator, the occurrence of maternal fever, neonatal seizures,

and oxygen requirement are familiar categoric measures of outcome. Disease-specific but limited tools have been developed.[12] A more universal, continuous measure, applying both to the mother and infant, seems preferable over categoric measures or scores with arbitrary weighting of the variables. Cost identification would be such a method if it is useful in capturing the resources used and their relationship to future health status. This paper does not address the long-term implications of this charge identification but is the next logical step in evaluation of this measure. It should also be noted that hospital charges are only indicative of resources used and not of total perinatal cost.

Great controversies have developed around the methods of childbirth, usually centered on the questions of mortality and morbidity with little objective comparative data. A standardized, population-based parameter may help resolve the morbidity aspect of these difficult clinical questions given specific risk factor or diagnostic information. The clinical challenge is to choose the method with both the lowest mortality and the lowest short- and long-term morbidity given specific risk information for both the mother and infant.

This study demonstrated the utility of using hospital charges as a measure of acute childbirth morbidity during a period when the frequency of primary cesarean delivery was increasing. The major factor apparently responsible for this increase was an increasing concern about fetal outcome.[11] This analysis would support the use of primary cesarean section for the common intrapartum indications. Less clear would be the use of primary cesarean delivery for patients with chronic hypertension and in patients with a preterm infant. Antepartum risk factors affect the incidence of the use of the procedure and its associated morbidity.

Because it is unlikely that prospective, randomized studies will be carried out for primary cesarean delivery for a given diagnosis or risk factor, the strategy for evaluation of this technology will likely fall to comparative studies of outcome.

The necessity of a reliable measure of morbidity seems obvious. Population-based studies of diagnostic- or risk-specific delivery procedures should be carried out along with longitudinal studies of long-term outcome of this technology. The use of these methods could be applied to other hospital-based technologies.

Discussion

Dr. Stephen S. Entman, Nashville, Tennessee. The issues that Dr. Hage raises may be the most important issues that will be discussed in this meeting and will progressively dominate all medical meetings. Although the current focus of attention for health care economists relates to the unfunded and underfunded segment of the population, it is very clear that there are only finite resources available for taking care of our population. Expenditures in one area will necessarily detract from the resources available for other areas. It is incumbent on us, as leaders within our specialty, to scrutinize the practice patterns that we have previously endorsed, many of which were initially well intended but have since been extrapolated beyond that original intent and applied without attention to either cost or real benefit. Thus Dr. Hage's quote from Dr. Bunker's book relating to the effectiveness of treatment, particularly where uncertainty leads to professional disagreement, is the critical point for the 1990s.

Although I agree with the spirit of Dr. Hage's topic, I have some semantic and methodologic concerns about the way in which he developed the theme in the manuscript. I have a semantic concern about the title and the attempt to relate charges as an index of morbidity. Morbidity is defined as relating to disease or to disease caused by an event. It would seem to me that Dr. Hage's use of the term morbidity primarily refers to the financial health of the individual and of society and not to an index of disease state. A title such as "Financial implications of clinical decisions: Cesarean section" might be more true to the purpose.

I also have several questions about the methodology used. The first relates to Dr. Hage's use of hospital charges rather than hospital costs. In my experience, hospitals have charge structures that do not necessarily reflect costs or even resources; there are markups that are differentially calculated for different activities. Specifically, vaginal deliveries are frequently charged with minimal markup, as a loss leader to draw families into the hospital care network. Frequently disposable items, more of which are used during a cesarean section, are marked up as a major profit center. Therefore, unless the ratio of charges to costs was consistent between the two modes of delivery, there may be bias in the data as presented.

My second question relates to the possibility of a systematic bias in the attrition of patient data from the sample. Although data were unavailable from 11% of all deliveries, 14% of cesarean sections were lost compared with only 10% of vaginal deliveries. This is both statistically and quantitatively significant.

It is not clear from the manuscript how many patients were included in each category of risk factor for cesarean section. Was the analysis controlled for all variables that might influence the impact of an individual patient on the financial data set? For example, would a 31-year-old nulliparous woman who was referred for chronic hypertension at 30 weeks and who had oxytocin induction with a prolonged latent phase and subsequently underwent cesarean section for fetal distress be counted in all eight categories of risk? If so, her data will affect the distribution of data in every category.

One of the risk factors noted was referral of patients. Some of these patients, as well as some indigenous patients, probably had antepartum hospitalizations up to the date of delivery. Were the charges for these antepartum stays removed from the data analysis? These charges, which could be considerable, are effectively independent of the decision for route of delivery. Therefore, it would be inappropriate to include them in an analysis of resources associated with cesarean section. Similarly, although fetal condition may influence the mode of delivery, neonatal charges are essentially independent of route of delivery. As was noted, the infant charges can have a significant impact on the total charges. Whatever point one might make about the excessive use of resources for cesarean section can be significantly blunted by the magnitude of antepartum and neonatal charges, both of which are governed more by severity of the underlying condition than by the delivery.

I certainly support Dr. Hage's attempts to address these issues. I would suggest that he apply corrections to the financial data to account for case mix severity and length of stay and to segregate the phases of care and address them independently. With these corrections, the data may normalize and allow him to express consumption of resources in units that may be more relevant to the question: mean charges per day and mean charges per discharge. I hope that he will pursue this effort to improve our understanding of how costly our obstetric practice patterns are and to encourage us to confirm the real benefits of the things we do to take care of patients.

Dr. Larry P. Griffin, Indianapolis, Indiana. This very complex examination of the relationship between hospital charge data and acute morbidity related to childbirth clearly demonstrates the difficulties with which health planners are faced in attempting to predict future health care costs.

In 1990 Richard D. Lamb, Director of the Center for Public Policy and Contemporary Issues at the University of Denver, published a discussion of a number of economic issues that face all of us in the practice of medicine as we enter the next century.[1] Nearly 12% of the gross national product in the United States is spent on health care, and health care costs continue to rise at a rate far greater than for other goods and services. In addition, age- and sex-adjusted mortality rates have not decreased in proportion to this dramatic increase in medical care costs. Perhaps as important is the fact that tax funds, either state or federal, provide 42% of the nation's health resource funds, a dramatic increase from the 26% provided in 1965. As a result, payors, both private and public, are closely examining the manner in which health care dollars are being spent.

Reproductive related health care constitutes 5.5% of the total health care expenditures in this country.[2] The largest categories of reproductive-related health care expenditures are obstetric care, which comprises 46% of reproductive health expenditures, and infant care, which is another 37% of these costs.

> To paraphrase Rashi Fein, we live in a society, not an economy. We must ultimately look at the larger canvas and decide; how do we spend limited resources to the highest benefit?[1]

We clearly are faced with a challenge.

Among other, more politically sellable and (to physicians) emotionally appealing health care solutions, such as reforming tort law, is the emphasis on more effective uses of health care dollars.

The American Medical Association is currently attempting to develop practice parameters in conjunction with many specialty societies to help to provide a yardstick for appropriate types of care in certain conditions. Although these exercises have some theoretic benefit in providing protocols for some standardized methods of care, many argue that this cookbook type of medicine tends to breed mediocrity rather than support the innovative approach that has served American medicine so well.

More apparent, however, are the economic benefits to be obtained by establishing practice parameters for specific conditions. The issue seems not whether we

need to evaluate the cost and therapeutic effectiveness of our approaches but rather how best to do this.[3,4]

Dr. Hage and his coinvestigators, along with others, have previously described significant changes in the rate of performance of cesarean delivery,[5] as others have done in regard to numerous other types of invasive procedures. Clearly, the conclusions of this article are useful. More important, however, is the demonstration of an approach to begin to analyze in some systematic, objective fashion the economic aspects of health care related to obstetrics and the multiple variables that must be considered in producing a useful model.

There are some limitations of the study, however. The failure to take into consideration over the period of the study the increases in charges related to inflation, incremental differences in the rate of change of specific hospital charges, changes in the length of stay for a given condition, and charges for outpatient services in addition to others bring the absolute reliability of the conclusions of the study into question. In addition, changes in the patterns of obstetric practice might be expected to produce different charges for the same diagnosis. Finally, prophylaxis for potential complications alone may be expensive, and no attempt was made to assess the cost of prophylactic measures on patients with specific risk factors, because many of these would be delivered in an ambulatory setting.

Additionally, the assessment of morbidity implies degree, yet no attempt was made to analyze indirect costs such as nursing care. For example, it costs an institution more in nursing time to take care of an ill patient than one who is simply occupying a bed, yet the basic charge for a hospital day is the same. Conversely, the most severe degree of morbidity, death, might be associated with lower hospital charges than seen in a patient with moderate complications.

As a result, I am concerned about the use of the term morbidity interchangeably with the concept of charges. This study in my opinion does not indicate they can reasonably be interchanged without significant confusion.

Finally, the huge differences between cities in charges for the same procedure, and even between different institutions within the same city, prevent this particular model from being a useful tool on a national or even regional basis without significant sophistication of technique. In an individual institutional setting, however, there may be useful extensions. Such an analysis, for example, might be used as an indicator of quality assurance to reflect various levels of high-risk care in response to the frequent justification for high cesarean delivery rates because of the high-risk nature of the patient population.

The authors are to be congratulated and encouraged in their work. As increased emphasis is placed on the cost effectiveness of various treatment modalities, and, as the development of practice parameters continues, accurate analysis of the economic costs of our treatment decisions is critical if we are to play a role in planning the future of health care delivery in this country.

I do have a couple of questions for the authors. (1) Have you attempted to use this technique on a total care basis (i.e., inpatient and outpatient for a specific procedure and diagnosis, visiting nurses, pharmaceuticals) to compensate for trends toward early hospital discharge and ambulatory or home care? (2) Might not costs be a better indicator than charges because charges vary much more from institution to institution than do costs for providing the service? (3) How can you reasonably adjust for interhospital differences in charges, which have been shown to range up to 1600% markups for some items in some institutions? (4) What do you see as the future direction of these types of economic studies in your institution?

DR. HAGE (Closing). The issue of the economic aspects of care are going to continue to be an important part of the real world of practice, and how we respond is going to be very important.

Let me address what I think is a common issue of both the discussants, the semantics and the meaning of morbidity. It's difficult to have a clear definition of morbidity. A practical definition that I used was the increased use of resources to attempt to bring the patient back to a healthy state. That is a somewhat arbitrary definition and certainly still hypothetic. The reason for this definition is to attempt to encompass the costs of morbidity and its severity. As has been correctly pointed out, charges do not equal costs, so that hospital charges are only a proxy estimate of morbidity and morbidity severity.

Second was the question of bias because of the loss of patients and the method of analysis. The loss of information was related to the merging of two data sets and not from any exclusion of patients. I don't know of any way to prevent that except that as data bases are being developed multiple unique markers of patients and their babies should be included

Last, the use of hospital charges has beeen reported in the evaluation of the effectiveness of a perinatal intervention. Two examples are artifical surfactant

therapy[1] and the use of β-sympathomimetics for prevention of premature labor.[2] Their analysis methods have not been able to get around the problem of the skewed distributions of charges. The statistical method of this paper allowed the modeling of these distributions and the development of the morbidity index with the predicted median and its 95% confidence intervals. The utility of this method and this type of study should be verified at other centers and with other data sets of perinatal information.

Treatment of fetal supraventricular tachycardia with flecainide acetate after digoxin failure

To the Editors: After reviewing the interesting case report by Kofinas et al. (Kofinas AD, Simon NV, Sagel H, Lyttle E, Smith N, King K. Treatment of fetal supraventricular tachycardia with flecainide acetate after digoxin failure. AM J OBSTET GYNECOL 1991;165:630-1), readers may be interested in a further case of fetal supraventricular tachycardia treated by maternal administration of flecainide after unsuccessful treatment with digoxin that was reported in the British literature.[1] A 26-year-old gravida 2, para 1 woman at 28 weeks' gestation had fetal tachycardia >200 beats/min on routine auscultation with a Pinard stethoscope. Fetal M-mode echocardiography showed a ventricular rate of 240 beats/min with a 1:1 atrioventricular relation. The heart was structurally normal, but moderate pericardial effusion and ascites were noted. The mother was given three oral doses of digoxin 500 μg every 8 hours and then 500 μg daily. Echocardiography showed a persistent supraventricular tachycardia in spite of trough maternal serum digoxin levels of 1.5 μg/L and amniotic fluid levels of 0.2 μg/L. Flecainide 110 mg (1.4 mg/kg) was then given intravenously under maternal echocardiography and fetal echocardiographic control. Fetal sinus rhythm at 120 beats/min supervened. Oral flecainide 100 mg every 8 hours was substituted for digoxin treatment. Trough maternal serum flecainide concentration was 656 μg/L (adult therapeutic range 400 to 1000 μg/L). The fetus stayed in sinus rhythm, and all traces of pericardial and ascitic effusion resolved within 10 days. Labor was induced at 38 weeks' gestation. A 12-lead electrocardiogram on the 3450 gm female infant showed sinus rhythm with no evidence of preexcitation. Concentrations of flecainide in maternal and cord plasma obtained simultaneously 5 hours after the last oral dose were 833 and 533 μg/L, respectively, confirming good transplacental passage of flecainide. The baby remained in sinus rhythm without further medication.

Reply

To the Editors: I thank Mills for his interest in our article. We are aware of his case and another case published by Wren and Hunter.[1] Unfortunately, the JOURNAL allows only two references in brief communication articles, and we chose the two that were most appropriate for our paper.

We believe that flecainide acetate is a safe alternative for fetuses with hydropic changes unresponsive to digoxin. Flecainide acetate has been associated with lethal ventricular tachyarrhythmias in patients who received it to suppress arrhythmias caused by myocardial infarction. Certainly we must keep this in mind for maternal safety, but it is very unlikely that the heart of a healthy pregnant woman would be subject to the same effect. It is prudent, however, to administer this medication in a hospital setting under electrocardiographic observation of the maternal heart, especially when the medication is administered intravenously. Baseline electrocardiography before treatment with follow-up studies until therapeutic levels are achieved in the mother may be satisfactory in patients who receive the medication orally.

For these reasons it becomes clear that flecainide acetate should be used in the treatment of fetal supraventricular tachycardia only when other safer measures have failed to help the fetus. We hope that future cases will also be published so that we can gain more experience with the use of this medication and increase its safety margin.

Amniotic fluid glucose and intraamniotic infection: Sensitivity, specificity, and predictive values

To the Editors: I read with interest the article by Kirshon et al. (Kirshon B, Rosenfeld B, Mari G, Belfort M. Amniotic fluid glucose and intraamniotic infection. AM J OBSTET GYNECOL 1991;164:818-20). It seems to me that in Table II the authors have incorrectly calculated the sensitivity, specificity, and positive and negative predictive value of their data. Nine patients had infections, and all had amniotic fluid glucose levels <10 mg/dl; this implies a sensitivity of 100% and not 75% as calculated by the authors. Likewise, 27 of 30 patients without infection were correctly identified by amniotic fluid glucose levels >10 mg/dl, a specificity of 90% and not 100%. Low glucose levels predicted 9 of 12 patients with infection, hence a positive predictive value of 75% and not 100%. Similarly, glucose levels >10 mg/dl correctly predicted the absence of infection in 27 of 27 patients, a negative predictive value of 100% and not 90%.

Reply

To the Editors: We agree with Gonen's findings. Table II (page 819) should read as follows:

Positive predictive values	9/12 (75%)

Negative predictive values	27/27 (100%)
Sensitivity	9/9 (100%)
Specificity	27/30 (90%)

We thank Gonen again for his letter.

Ureaplasma urealyticum resistance to erythromycin: Confirmed by clinical trial

To the Editors: The article by Eschenbach et al. (Eschenbach DA, Nugent RP, Rao AV, et al. A randomized placebo-controlled trial of erythromycin for the treatment of *Ureaplasma urealyticum* to prevent premature delivery. AM J OBSTET GYNECOL 1991;164:734-42) was inappropriately titled. It should have been titled "*Ureaplasma urealyticum* resistance to erythromycin: Confirmed by clinical trial."

Ostensibly a megabucks clinical trial was done involving five medical centers with the object of eradicating ureaplasmas in test patients versus placebo-treated patients. The reference to eradication by tetracycline was cited by the authors,[1] yet erythromycin was used in the study.

Strange that not one of the 29 people listed as either coauthors or members of the Vaginal Infections and Prematurity Study Group suggested the use of antibiotic susceptibility testing of the ureaplasmas before initiating antibiotic administration. It seems to be poor medical practice to treat empirically, especially because resistance to erythromycin is common among the current isolates of ureaplasmas in the United States.

Our laboratory isolates and processes approximately 5000 cultures of ureaplasmas and mycoplasmas a year and does antibiotic susceptibility testing routinely: we have found erythromycin resistance to be so high among *Ureaplasma* isolates that erythromycin is never suggested as appropriate therapy. In our latest 1600 consecutive antibiotic susceptibility tests of *Ureaplasma* isolates, 86% of the strains were resistant to erythromycin. Of 400 *Mycoplasma hominis* strains, 100% were resistant.

We are extremely pleased to see that our in vitro findings have been confirmed by in vivo trials.

Tetracycline and doxycycline are the antibiotics of choice assuming the microorganisms are susceptible (15% are not). Those antibiotics are not usually used during pregnancy. Ideally, therefore, the ureaplasmas and mycoplasmas should be eradicated before conception.

Reply

To the Editors: Since the discovery of *Ureaplasma urealyticum* in 1937, reports on these microorganisms have generated more controversy than definitive results. *U. urealyticum* are ubiquitous in the female genital tract, and their isolation from 70% to 80% of pregnant women could even raise the question of whether they should be considered part of normal vaginal flora. They are commonly isolated from the chorioamnion of women with chorioamnionitis. In certain settings such as septicemia, pneumonia, and chronic lung disease in premature neonates, postpartum bacteremia in women and nongonococcal urethritis in men, *U. urealyticum* has been associated with disease. However, given their frequency in the vagina, the attack rate for disease appears to be exceptionally small.

We recently reported the results of a large National Institutes of Health–supported multicenter study of vaginal infections and prematurity in which *U. urealyticum* (in the vagina of 72% of >8000 women) was associated with no increase in prematurity or postpartum or neonatal disease.[1] It was not unexpected to find that the administration of erythromycin compared with placebo for a mean of 36 days also had no effect upon the incidence of prematurity or postpartum or neonatal disease.[2]

Kundsin et al. asked whether another antibiotic might have produced different results. Data from their laboratory suggest a high frequency of *U. urealyticum* resistance to erythromycin. Erythromycin was chosen to treat *U. urealyticum* in the National Institutes of Health study because it had previously been associated with a reduction of prematurity when used to treat *U. urealyticum*.[3] In contrast to Kundsin's data, others have consistently reported that erythromycin is active in vitro against *U. urealyticum*.[4,5] Further, erythromycin is one of the few drugs active against the microorganism that can be safely used in pregnancy. *U. urealyticum* is resistant to β-lactams because they lack peptidoglycan and to sulfonamides because they do not synthesize folic acid. As might be expected, differences of opinion occur over variations in susceptibility testing, but in most reports 72% to 97% of *U. urealyticum* are considered susceptible or moderately susceptible to erythromycin.[4-6] In comparison, moderate to good susceptibility has been reported to be 81% to 93% for tetracyclines, 97% for chloramphenicol, 47% for clindamycin, and 36% for ciprofloxacin.[4-6] Thus except for erythromycin, drugs effective in vitro are either contraindicated or too toxic for use in pregnancy.

If *U. urealyticum* is inhibited in vitro by erythromycin, why did prolonged erythromycin treatment not eliminate *U. urealyticum* from the vagina? Although we ad-

vanced numerous theories,[2] careful follow-up has revealed similar high-failure rates among pregnant women treated with erythromycin[3] and among nonpregnant women treated with tetracyclines.[5] Should we wait for more data? In clinical practice it would be difficult to recommend screening or treating vaginal *U. urealyticum* given the current data. Of course, if additional data become available this recommendation would be reevaluated.

Umbilical artery flow velocity after vibratory acoustic stimulation

To the Editors: We read the article by Gagnon et al. (Gagnon R, Morrow R, Ritchie K, Hunse C, Patrick J. Umbilical and uterine artery blood flow velocities after vibratory acoustic stimulation. AM J OBSTET GYNECOL 1988;159:574-8) with considerable interest. They concluded that the decrease in umbilical peak-systolic/end-diastolic ratio was the result of fetal tachycardia rather than a change in the placental vascular resistance. We agree that umbilical artery blood flow velocity decreases significantly after vibratory acoustic stimulation; this decrease coincides with the significant increase in instantaneous fetal heart rate (FHR) value.

Our recent study (unpublished data, 1991), however, showed that there was significant decrease in resistance index in the umbilical artery even when resistance index was corrected with FHR value. In our series of 476 normal pregnant women there was a significant ($p < 0.001$) difference in mean resistance index in the umbilical artery before vibroacoustic stimulation and after stimulation. We corrected the resistance indexes of both groups according to FHR value with two methods.

We selected the samples of resistance index according to the same FHR value (150 to 160 beats/min) from both groups. The mean resistance index of prestimulation samples was 0.570 ± 0.071 ($n = 81$); that of poststimulation samples was 0.548 ± 0.067 ($n = 96$). The significant ($p < 0.001$) difference remained between two samples. The mean resistance indexes of two samples, however, might not reflect those of both original groups because these samples of both groups consisted of different cases.

Therefore we corrected the mean resistance indexes of the total cases ($n = 476$) by means of negative correlation between resistance index and FHR value. The mean corrected resistance index of prestimulation was 0.568 ± 0.066; that of poststimulation was 0.547 ± 0.063. The significant ($p < 0.001$) difference still remained between those two groups after correction.

These data suggested that any causes other than fetal acceleration might decrease the resistance index after vibroacoustic stimulation.

Reply

To the Editors: We thank Nakamura et al. for their interest in our article and the opportunity to discuss some aspects of the relationship between instantaneous FHR value and umbilical artery Doppler flow velocity waveforms.

Our initial study was designed only to determine whether vibratory acoustic stimulation could significantly alter umbilical artery Doppler flow velocity waveforms. We concluded that vibratory acoustic stimulation decreases the umbilical artery peak-systolic/end-diastolic ratio at the same time FHR increases; our data suggested that the changes seen in umbilical artery peak-systolic/end-diastolic ratio after vibratory acoustic stimulation were caused by changes in FHR rather than changes in placental vascular resistance. Subsequently, similar observations have been made by Wladimiroff and Cheung[1] in the fetal internal carotid artery with the pulsatility index. However, when the pulsatility index was standardized for a FHR of 140 beats/min, the fetal internal carotid artery pulsatility index remained virtually unaltered. They concluded that vibratory acoustic stimulation did not alter fetal cerebral vascular resistance, but only FHR.

In a subsequent article we demonstrated that the relationship between FHR and umbilical artery peak-systolic/end-diastolic ratio was curvilinear and that FHR had a significant effect only on the end-diastolic component of the waveform and not on the peak-systolic component. The results displayed in Nakamura et al. regarding the effect of vibratory acoustic stimulation

on the umbilical artery resistance index, after correction for FHR being made, involved a large number of patients and demonstrated a modest effect (3.5% decrease) of vibratory acoustic stimulation on umbilical artery resistance index. Our previous study involved only 11 women; with a coefficient of variation between 6% and 8% during control observations, we would not have been able to detect such a small difference. In addition, with a large number of subjects it is well known that a small effect could be statistically significant but of no clinical or physiologic significance. The reverse is also true. With a small number of subjects, a large effect could be statistically insignificant but of high clinical or physiologic significance.

For these reasons we maintain our initial conclusion that vibratory acoustic stimulation does not alter placental vascular resistance; it only increases FHR with a subsequent increase in the end-diastolic component of the waveform. As a result of these changes in FHR any Doppler-derived index of vascular resistance of any fetal blood vessel would probably suggest a decrease in downstream vascular resistance after vibratory acoustic stimulation. However, interpretation should take into account other physiologic variables that could alter these waveforms, such as FHR.

Steroids receptors in the endometrium during clomiphene citrate treatment

To the Editors: In a recent article Fritz et al. (Fritz MA, Holmes RT, Keenan EJ. Effects of clomiphene citrate treatment on endometrial estrogen and progesterone receptor induction in women. Am J Obstet Gynecol 1991;165:177-85) indicated that there has been no effect on endometrial estrogen and progesterone receptors in luteal phase after ovulation induction with clomiphene citrate 150 mg/day from cycle days 5 to 9 compared with normal ovulatory cycles.

We have awaited this logical observation since Aksel et al.[1] and Roennberg et al.[2] reported reduced levels of receptors after treatment with clomiphene citrate.

We have immunohistochemically examined the effect of adjuvant breast cancer treatment with another antiestrogenic agent, tamoxifen citrate, 40 mg/day on the postmenopausal endometrium and found that it markedly induced more progesterone and estrogen receptors when compared with an untreated control group (unpublished data).

This increase in progesterone and estrogen receptors may be caused by the partial estrogenic agonist action of these antiestrogens and may explain the increasing risk of endometrial carcinoma in this group of patients.[3]

The study by Fritz et al. also showed that both estrogen and progesterone receptors in the late luteal phase were similarly reduced in both normal ovulatory and clomiphene citrate–stimulated cycles. Press et al.[4] attributed this phenomenon to the suppressive effect on receptors associated with the increased level and activity of progesterone in the second half of the cycle.

Those who noted reduced receptors after clomiphene citrate in the infertile patient might have missed the improvement of progesterone secretion associated with the recruitment of more follicles in treatment cycles.

That the Fritz et al. study found no change in the receptor status in spite of the increased level of progesterone in the clomiphene citrate–stimulated cycle may represent a relative increase of receptors because the expected reduction of receptors did not occur. This finding is supported by our own observations.

Alternatively, the findings of Fritz et al. could be explained by the short duration of clomiphene treatment, hence the less vigorous progesterone level and activity (one cycle only). The duration of treatment and the clomiphene citrate dose might have an impact on the receptor status of the endometrium.[4]

Reply

To the Editors: We thank Shabib and Pitrof for their interest in our work. Their immunohistochemical evidence for increased concentrations of endometrial estrogen and progesterone receptor in postmenopausal women receiving adjuvant breast cancer treatment with tamoxifen is interesting and consistent with our previous observations that estrogen receptor concentrations (as determined by quantitative immunoassay) are higher in breast cancer recurrences obtained from patients receiving tamoxifen.[1] Indeed, increased steroid receptor concentrations in these patients receiving chronic antiestrogen therapy might be attributed to the partial estrogen agonistic activity ascribed to tamoxifen or its metabolites. Alternatively, chronic antiestrogen

therapy may produce increased serum levels of estrogenic steroids in some breast cancer patients.[2]

There are several possible explanations for our findings of similar midcycle and late secretory phase endometrial estrogen and progesterone receptor concentrations in control and clomiphene treatment cycles. The suppressive effects of increased circulating progesterone levels or persistent estrogen antagonism by residual clomiphene may have prevented any increase in receptor induction that otherwise might accompany the markedly higher estrogen concentrations after clomiphene treatment. Conversely, maximal concentrations of endometrial steroid receptor may be induced by normal ovulatory threshold levels of estradiol; elevated estrogen levels may have offset any decline in receptors caused by the increase in progesterone or clomiphene's antiestrogenic action. As Shabib and Pitroff suggest, the absence of a reduction in receptor levels after clomiphene treatment in spite of the marked increase in serum progesterone could also, in part, reflect the estrogenic activity linked to clomiphene or a metabolite with similar activity.

Our data, together with those of Hecht et al.,[3] demonstrated that the many and competing direct and indirect effects of clomiphene treatment have no net impact on midcycle, midluteal, or late luteal endometrial steroid receptor concentrations in normally cycling women. We agree that dose- and time-dependent adverse effects of clomiphene treatment on endometrial steroid receptor populations have not been excluded. Although Hecht et al.[3] observed no adverse effects with either low- or high-dose clomiphene, our study clearly demonstrated the potential for significant systemic accumulation of clomiphene or its metabolites after repeated cycles of administration. Consequently the effects of experimental acute clomiphene administration in normal women may well differ from the effects in anovulatory individuals who receive longer-term treatment.

The tip of the iceberg and the best fit in ultrasonographic dating of pregnancy

To the Editors: Goldstein (Goldstein SR. Embryonic ultrasonographic measurements: crown-rump length revisited. Am J Obstet Gynecol 1991;165:497-501) has revisited crown-rump length measurements and found that currently used tables for dating pregnancy are invalid at gestational ages of <8.5 weeks.

Whenever a new technical device is offered to the medical profession new methods are developed to make the device a usable tool. In the early stages the necessary time is not always taken to assure that these methods satisfy the most stringent criteria. Therefore these methods should be considered preliminary until better and more biologically correct methods are developed.

Admittedly, with the concomitant introduction of computers and obstetric ultrasonography, the fastest and easiest way to make dating equations was to take the measurements from the ultrasonogram and the supposedly good dates to a computer and try to obtain the best fit by using different polynomials in linear regression analyses. The best-fit equation became the dating equation used to make the tables.

Whether the parameter was crown-rump length, biparietal diameter, head circumference, or femur, there was a serious problem. Because polynomials cannot be extrapolated it became important to include as many early measurements as possible to expand the usefulness of the new dating equation. By measuring only the largest fetuses of the early population and not realizing that only the tip of the iceberg was measured investigators were blinded by very low random errors. The equations were generally accepted because the computers displayed excellent fits above anything seen in obstetrics before. Thus the "cult of the best fit" was born.

Methods are, however, not evaluated by their random errors. The systematic errors created by the selection of only the largest measurements in early pregnancy had to be balanced by an opposite systematic error later in pregnancy by the analytic method.

With an abdominal transducer and patient material with known date of ovulation examined and analyzed longitudinally, biologic (linear) dating curves were made for the gestational sac, crown-rump length,[1] biparietal diameter, mean head diameter,[2] and femur length.[3] Made before the general introduction of vaginal probes, these simple dating functions have proved to have full validity for measurements even before a gestational age of 6 weeks. Because of the rapid growth of the crown-rump length, the almost C-shaped curve of the fetus will not reduce the assessment of gestational age by >1 or 2 days, well within the variability limits.

Ivar K. Rossavik, MD, PhD

Reply

To the Editors: Rossavik's work in statistical analysis relative to pregnancy dating is well-known and respected, as is evidenced by his reference list. I am compelled, however, to make the following statements:

(1) The opinion I expressed was that use of the terminology "crown-rump length" is inappropriate before long-axis measurement of 18 to 22 mm when a true crown and rump are discernable.[1]

(2) The appreciation of the correct anatomic structures and appearance can only enhance the accuracy and scientific appropriateness of current or future measurements, especially in light of newer highly magnified endovaginal probes and the "sonomicroscopy" they afford.

(3) Rossavik states that "because of rapid growth of the crown-rump length, the almost C-shaped curve of the fetus will not reduce the assessment of gestational age by >1 or 2 days, well within the variability limits." When compared with Robinson and Fleming[2] our data suggest an *increase* in gestational age by 2 to 3 days[3] (presumably caused by the new understanding, and thus careful noninclusion, of the adjacent yolk sac). Although this is within variability limits, the effect is to shift the mean (and thus the entire confidence limit).

Hydroxyurea and pregnancy

To the Editors: Patel et al. (Patel M, Dukes IAF, Hull JC. Use of hydroxyurea in chronic myeloid leukemia during pregnancy: a case report. Am J Obstet Gynecol 1991;165:565-6) reported a patient with chronic myeloid leukemia in whom hydroxyurea was used during pregnancy with a successful outcome for both mother and fetus. We would like to report a similar observation of a woman with chronic myeloid leukemia who was administered hydroxyurea at conception and throughout pregnancy.

Hyperleukocytosis was found during the course of a biologic assessment in a 30-year-old woman who complained of sterility. Chronic myeloid leukemia was diagnosed in August 1984. Results of the Philadelphia chromosome test were positive. None of her siblings were histocompatible and hydroxyurea was given (1 to 2 gm/day) while the search for an unrelated bone marrow donor was initiated. Four years later the patient became pregnant. After receiving precise information about the potential fetal risk of hydroxyurea treatment and about the prognosis of her disease, she eagerly refused a therapeutic abortion. During pregnancy hydroxyurea could not be discontinued in view of dose-dependent thrombocytosis and hyperleukocytosis; the dosage ranged from 1 to 3 gm/day. At 15 weeks of pregnancy cytogenetic analysis of amniotic fluid showed a normal 46,XY karyotype. Shortly after, splenalgia and increasing splenomegaly led to low-dose radiotherapy of the spleen (1.5 Gy), which had an obvious, albeit transient, beneficial effect. A cesarean section was planned at 38 weeks of gestation for obstetric reasons, and hydroxyurea was discontinued 1 week before delivery to alleviate a potential cytopenia in the fetus. The patient was delivered of a male infant with a birth weight of 3100 gm and normal clinical status who thereafter experienced normal growth and development (follow-up 32 months). Hematologic assessments of umbilical cord blood samples and blood samples taken during the first week of life showed normal results.

In our patient, as in the patient of Patel et al., continuous administration of hydroxyurea before and throughout pregnancy had neither teratogenic effects nor hematologic consequences on the fetus. Teratogenic effects of hydroxyurea have been demonstrated in mammals when given at the onset of gestation and at doses at least five times those commonly used in humans.[1-3] However, clinical reports in humans have shown that the risk of teratogenicity was often overestimated: In none of the hitherto published cases was any untoward effect observed on the course of pregnancy or on the fetus.[4]

Recent demonstration of the potential beneficial effects of hydroxyurea in sickle cell disease by the bias of a decrease in hemoglobin S/hemoglobin F ratio[5] has recently led to a reappraisal of the adverse effects of its chronic administration in young women. If available, other cases of hydroxyurea administration throughout pregnancy for hematologic malignancies should be collected before any consensus is made on new therapeutic approaches in young women with sickle-cell disease.

ITEMS

Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of $60.00 U.S. per insertion and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to Kay G. Goehler, Senior Manuscript Editor, Journal Editing, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318.

The Harvard Medical School, Department of Continuing Education, and The Massachusetts General Hospital, Department of Gynecology, are presenting a postgraduate course in: Vaginal Surgery, directed by David H. Nichols, MD, on October 9, 10, 11, 1992, at The Ritz-Carlton Hotel, Boston, Massachusetts. For information contact: Harvard Medical School, Department of Continuing Education. Tel.: (617) 432-1525.

The Thomas Garite/Roger Freeman Obstetrical Symposium, October 23 and 24, 1992, Claremont Resort, Berkeley, California. Sponsored by Alta Bates Medical Center. For information contact: Mary Grim, Medical Education Program Manager, tel.: (510) 204-1420.

Courses sponsored by University of California, Irvine, and Long Beach Memorial Medical Center. For information contact the Center for Health Education. Tel.: (310) 595-3811.

July 29–August 1, 1992, 10th Controversies OB/GYN, Mauna Kea, Hawaii
November 16-21, 1992, 15th Annual OB/GYN Review, Costa Mesa, California
January 13-17, 1993, 8th Annual Perinatal Symposium, Beaver Creek, Oregon
February 27–March 6, 1993, 14th Annual Current Topics in OB, Aspen, Colorado
March 25-27, 1993, Gynecologic Surgery, Rancho Las Palmas, California

Perinatal dilemmas, a national conference of interest to both physicians and nurses in the fields of Obstetrics and Neonatology, August 10-14, 1992, at the Snow King Resort, Jackson Hole, Wyoming. ACOG and ANA approved. For complete brochure or to register contact: Contemporary Forums, 11900 Silvergate Dr., Suite A, Dublin, CA 94568. Tel.: (510) 828-7100.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1992 issues from the Publisher, at a cost of $68.00 for domestic, $95.76 for Canada, and $91.00 for international for Vol. 166 (January-June) and Vol. 167 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351, or (314) 453-4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Subject index*

A

Abdominal injuries
Nonsurgical management of penetrating uterine trauma in pregnancy: a case report (Grubb). 1992;166:583-4

Abdominal pain
Long-term sequelae of acute pelvic inflammatory disease: a retrospective cohort study (Safrin et al). 1992;166: 1300-5
The resolution of chronic pelvic pain after normal laparoscopy findings (Baker and Symonds). 1992;166:835-6

Abnormalities
Bilateral choroid plexus cysts in trisomy 21 (Rotmensch et al). 1992;166:591-2
Hydrops fetalis associated with congenital myotonic dystrophy (Afifi et al). 1992;166:929-30
Maternal phenylketonuria collaborative study, obstetric aspects and outcome: the first 6 years (Platt et al). 1992;166:1150-62
Percutaneous umbilical blood sampling: results from a multicenter collaborative registry (Hickok et al). 1992;166: 1614-8
Prenatal diagnosis of autosomal recessive polycystic kidney disease: variable outcome within one family (Barth et al). 1992;166:560-7
Prenatal ultrasonographic findings associated with wide clefting of the upper two thirds of the fetal sternum (Mahone et al). 1992;166:1219-21
Receiver-operator characteristic, efficiency analysis, and predictive value of serum progesterone concentration as a test for abnormal gestations (Cowan et al). 1992; 166:1729-37
Spontaneous abortion and subsequent adverse birth outcomes (Thom et al). 1992;166:111-6

Abortion
Abortion or motherhood, suicide and madness (Ryan). 1992;166:1029-36
Depressive symptoms in women in the 6 months after miscarriage (Neugebauer et al). 1992;166:104-9
Early amniocentesis: outcome, risks, and technical problems at ≤12.8 weeks (Hanson et al). 1992;166:1707-11
In the rhesus monkey placental retention after fetectomy at 121 to 130 days' gestation outlasts the normal duration of pregnancy (Nathanielsz et al). 1992;166:1529-35
Incidence of pelvic inflammatory disease after first-trimester legal abortion in women with bacterial vaginosis after treatment with metronidazole: a double-blind, randomized study (Larsson et al). 1992;166:100-3
Sex selection and early pregnancy fetal sex determination: ethics and personal freedom of choice (Stephens) (Letter); (Evans and Fletcher) (Reply). 1992;166:1024-5
Spontaneous abortion and subsequent adverse birth outcomes (Thom et al). 1992;166:111-6

Abortion, habitual
Evidence of embryo- and trophoblast-toxic cellular immune response(s) in women with recurrent spontaneous abortion (Hill et al). 1992;166:1044-52
Frequency of positive antinuclear antibody test results in women with recurrent spontaneous abortions (Harger) (Letter); (Xu et al) (Reply). 1992;166:1021-2
Impact of histocompatibility antigens on pregnancy outcome (Eroglu et al). 1992;166:1364-9
Interlaboratory variation in antiphospholipid antibody testing (Peaceman et al). 1992;166:1780-7
Mechanism of recurrent spontaneous abortion. I. Ultrasonographic findings (Stern and Coulam). 1992;166: 1844-52
Prevalence of out-of-phase endometrial biopsy specimens (Peters et al). 1992;166:1738-46
Repeated fetal losses associated with antiphospholipid antibodies: a collaborative randomized trial comparing prednisone with low-dose heparin treatment (Cowchock et al). 1992;166:1318-23
Reproductive outcome in women with recurrent spontaneous abortions of alloimmune and autoimmune causes: preconception versus postconception treatment (Kwak et al). 1992;166:1787-98

Abruptio placentae
Abruptio placentae associated with perforated appendicitis and generalized peritonitis (Yaron et al). 1992;166:14-5

Abscess, pelvic; *see* **Adnexitis**

Absorptiometry, photon
Low-dosage micronized 17β-estradiol prevents bone loss in postmenopausal women (Ettinger et al). 1992;166: 479-88

Abstracts
12th annual meeting of the Society of Perinatal Obstetricians. 1992;166:273-478

Acid-base equilibrium
Does amniotic fluid analysis reflect acid-base balance in fetal blood? (Economides et al). 1992;166:970-3
The effect of fetal sepsis on umbilical cord gases (Meyer et al). 1992;166:612-7
Long-term acid-base measurements in the fetal and maternal baboon (Daniel et al). 1992;166:707-12

Acoustic stimulation
Umbilical artery flow velocity after vibratory acoustic stimulation (Nakamura et al) (Letter); (Gagnon et al) (Reply). 1992;166:1865-6

Acquired immunodeficiency syndrome
Papanicolaou smear abnormalities in ambulatory care sites for women infected with the human immunodeficiency virus (Marte et al). 1992;166:1232-7

Actocardiotocography
Actocardiotocographic monitoring of triplets during vaginal delivery (van Eyck and Arabin). 1992;166:1293-4

Adenocarcinoma
Comparison of adenocarcinoma and squamous cell carcinoma of the uterine cervix: a population-based epidemiologic study (Anton-Culver et al). 1992;166:1507-14

*January, part 1, 1-272; part 2, 273-478; February, 479-772; March, 773-1028; April, 1029-1314; May, 1315-1594; June, part 1, 1595-1948; part 2, 1949-2012.

Adenocarcinoma—cont'd
Human monoclonal antibody recognizing an antigen associated with ovarian and other adenocarcinomas (Smith et al). 1992;166:634-45
The utility of immunocytochemistry in invasive adenocarcinoma of the cervix (Tamimi et al). 1992;166:1655-62
Adenomyosis; *see* **Endometriosis**
Adenosine cyclic monophosphate
Catecholamines modulate epidermal growth factor–induced prostaglandin E_2 production in amnion-like (WISH) cells by means of a cyclic adenosine monophosphate–dependent pathway (Su et al). 1992;166:236-41
Partial hydatidiform moles have impaired differentiated function (human chorionic gonadotropin and human placental lactogen secretion) in response to epidermal growth factor and 8-bromo-cyclic adenosine monophosphate (Morrish et al). 1992;166:160-6
Adhesions
Comparison of the peritoneal cells elicited by oxidized regenerated cellulose (Interceed) and expanded polytetrafluoroethylene (Gore-Tex Surgical Membrane) in a murine model (Haney and Doty). 1992;166:1137-42
Administration, cutaneous
Comparison of transdermal and oral estrogen/progestin replacement therapy: effects on serum lipids and lipoproteins (Crook et al). 1992;166:950-5
Use of two types of estradiol-releasing skin patches for menopausal patients in a tropical climate (McCarthy et al). 1992;166:2005-10
Administration, intranasal
Bioavailability of nafarelin in healthy volunteers (Chaplin). 1992;166:762-5
Administration, intravaginal
Periconceptional exposure to topical 5-fluorouracil (Otaño et al) (Letter); (Plouffe et al) (Reply). 1992;166:263-4
Administration, oral
Comparison of transdermal and oral estrogen/progestin replacement therapy: effects on serum lipids and lipoproteins (Crook et al). 1992;166:950-5
Adnexitis
Incidence of pelvic inflammatory disease after first-trimester legal abortion in women with bacterial vaginosis after treatment with metronidazole: a double-blind, randomized study (Larsson et al). 1992;166:100-3
Long-term sequelae of acute pelvic inflammatory disease: a retrospective cohort study (Safrin et al). 1992;166:1300-5
Pelvic abscess complicating transcervical embryo transfer (Sauer and Paulson). 1992;166:148-9
Pelvic inflammatory disease: findings during inpatient treatment of clinically severe, laparoscopy-documented disease (Livengood et al). 1992;166:519-24
Pelvic inflammatory disease: trends in hospitalizations and office visits, 1979 through 1988 (Rolfs et al). 1992;166:983-90
Adolescence
Contraceptive compliance with a levonorgestrel triphasic and a norethindrone monophasic oral contraceptive in adolescent patients (Woods et al). 1992;166:901-7
Dysmenorrhea and use of oral contraceptives in adolescent women attending a family planning clinic (Robinson et al). 1992;166:578-83
Early menopause in long-term survivors of cancer during adolescence (Byrne et al). 1992;166:788-93
Is trichomoniasis often associated with bacterial vaginosis in pregnant adolescents? (James et al). 1992;166:859-63
Adrenal cortex hormones
Effects of antenatal thyrotropin-releasing hormone, antenatal corticosteroids, and postnatal ventilation on surfactant mobilization in premature rabbits (Seidner et al). 1992;166:1551-9
A randomized, placebo-controlled trial of betamethasone for the prevention of respiratory distress syndrome at 24 to 28 weeks' gestation (Garite et al). 1992;166:646-51
Adrenal hyperplasia, congenital
Rapid identification of deoxyribonucleic acid sequence differences in cytochrome P-450 21-hydroxylase (CYP21) genes with denaturing gradient gel blots (Reindollar et al). 1992;166:184-91
Age factors
Lp(a) lipoprotein: relationship to cardiovascular disease risk factors, exercise, and estrogen (Lobo et al). 1992;166:1182-90
Aged
Radical hysterectomy in the elderly patient: analysis of morbidity (Fuchtner et al). 1992;166:593-7
Alcohol
Influence of alcohol intake on postoperative morbidity after hysterectomy (Felding et al). 1992;166:667-70
Alkylating agents
Early menopause in long-term survivors of cancer during adolescence (Byrne et al). 1992;166:788-93
Alloimmune thrombocytopenia; *see* **Thrombocytopenia**
Alpha fetoproteins
The California Maternal Serum α-Fetoprotein Screening Program: the role of ultrasonography in the detection of spina bifida (Platt et al). 1992;166:1328-9
Maternal serum α-fetoprotein, β-human chorionic gonadotropin, and unconjugated estriol levels in midtrimester trisomy 18 pregnancies (Greenberg et al). 1992;166:1388-92
Ultrasonographic dating of pregnancy causes significant errors in Down syndrome risk assessment that may be minimized by use of biparietal diameter–based means (Reynolds et al). 1992;166:872-7
Unexplained elevated maternal serum α-fetoprotein is not predictive of adverse perinatal outcome in an indigent urban population (Phillips et al). 1992;166:978-82
Ambulatory care facilities
Papanicolaou smear abnormalities in ambulatory care sites for women infected with the human immunodeficiency virus (Marte et al). 1992;166:1232-7
The American Board of Obstetrics and Gynecology
New certifications: subspecialty of Critical Care. 1992;166:1888
New certifications: subspecialty of Gynecologic Oncology. 1992;166:1369-85
New certifications: subspecialty of Maternal-Fetal Medicine. 1992;166:1385-6
New certifications: subspecialty of Reproductive Endocrinology. 1992;166:1887-8
Recertifications: principal specialty. 1992;166:1888-91
American Gynecological and Obstetrical Society
Transactions of the tenth annual meeting of the American Gynecological and Obstetrical Society. 1992;166:1029-207
Amniocentesis
Early amniocentesis: outcome, risks, and technical problems at ≤12.8 weeks (Hanson et al). 1992;166:1707-11

Therapeutic amniocentesis in twin-twin transfusion syndrome appearing in the second trimester of pregnancy (Saunders et al). 1992;166:820-4

Amnion

Catecholamines modulate epidermal growth factor–induced prostaglandin E_2 production in amnion-like (WISH) cells by means of a cyclic adenosine monophosphate–dependent pathway (Su et al). 1992;166:236-41

Amniotic fluid

Amniotic fluid glucose and intraamniotic infection: sensitivity, specificity, and predictive values (Gonen) (Letter); (Kirshon) (Reply). 1992;166:1863-4

Does amniotic fluid analysis reflect acid-base balance in fetal blood? (Economides et al). 1992;166:970-3

Endothelin-1 and endothelin-2 levels are increased in the amniotic fluid of women with preterm labor and microbial invasion of the amniotic cavity (Romero et al). 1992;166:95-9

Eradication of *Ureaplasma urealyticum* from the amniotic fluid with transplacental antibiotic treatment (Romero et al). 1992;166:618-20

Infection and labor. VII. Microbial invasion of the amniotic cavity in spontaneous rupture of membranes at term (Romero et al). 1992;166:129-33

Intrapartum amniotic fluid index and its relationship to fetal distress (Robson et al). 1992;166:78-82

Mimicking low amniotic pressure by chronic pharyngeal drainage does not impair lung development in fetal sheep (Fisk et al). 1992;166:991-6

The relationship between acute inflammatory lesions of the preterm placenta and amniotic fluid microbiology (Romero et al). 1992;166:1382-8

Tumor necrosis factor in preterm and term labor (Romero et al). 1992;166:1576-87

Anaphylaxis

Latex anaphylaxis in an obstetrics and gynecology physician (Chen et al). 1992;166:968-9

Anemia

Acute posttraumatic fetal anemia treated with fetal intravascular transfusion (Del Valle et al). 1992;166:127-9

Effects of chronic maternal anemia on systemic and uteroplacental oxygenation in near-term pregnant sheep (Delpapa et al). 1992;166:1007-12

Anemia, hemolytic

Hemolytic disease of the fetus (Spinnato) (Letter); (Weiner) (Reply). 1992;166:1589-90

Human fetal bilirubin levels and fetal hemolytic disease (Weiner). 1992;166:1449-54

Anemia, sideroblastic

Successive pregnancies complicated by idiopathic sideroblastic anemia (Barton et al). 1992;166:576-7

Anesthesia

Inhibition of preimplantation mouse embryo development by isoflurane (Warren et al). 1992;166:693-8

Angiography

Angiographic embolization in the management of hemorrhagic complications of pregnancy (Gilbert et al). 1992;166:493-7

Angiotensin II

The blood pressure response to infusions of angiotensin II during normal pregnancy: relation to plasma angiotensin II concentration, serum progesterone level, and mean platelet volume (Ito et al). 1992;166:1249-53

Changes in human platelet angiotensin II binding sites associated with early pregnancy (Baker et al). 1992;166:255-6

Uterine and umbilical flow velocity waveforms in normotensive and hypertensive subjects during the angiotensin II sensitivity test (Erkkola and Pirhonen). 1992;166:910-6

Animal welfare

Animals and ethics: how society's attitudes have changed (Fritzsche) (Letter); (Maharry) (Reply). 1992;166:1312-3

The issue of animal rights and human rights (Heller). 1992;166:1588-9 (Letter)

Anoxia

Role of prostaglandins in the metabolic responses of the fetus to hypoxia (Hooper et al). 1992;166:1568-75

Anti-C; *see* **Antibodies**

Antibiotics

Direct inhibition of proteases and cervical plasminogen activator by antibiotics (Milwidsky et al). 1992;166:606-12

Eradication of *Ureaplasma urealyticum* from the amniotic fluid with transplacental antibiotic treatment (Romero et al). 1992;166:618-20

Erythromycin therapy in preterm premature rupture of the membranes: a prospective, randomized trial of 220 patients (Mercer et al). 1992;166:794-802

A review of premature birth and subclinical infection (Gibbs et al). 1992;166:1515-28 (Curr. dev.)

Antibodies

Sévere anti-C hemolytic disease of the newborn (Bowman et al). 1992;166:1239-43

Antibodies, antinuclear

Frequency of positive antinuclear antibody test results in women with recurrent spontaneous abortions (Harger) (Letter); (Xu et al) (Reply). 1992;166:1021-2

Antibodies, monoclonal

Human monoclonal antibody recognizing an antigen associated with ovarian and other adenocarcinomas (Smith et al). 1992;166:634-45

Anticancer drugs; *see* **Antineoplastic agents**

Anticonvulsants

Anticonvulsant effects of magnesium sulfate on hippocampal seizures: therapeutic implications in preeclampsia-eclampsia (Cotton et al). 1992;166:1127-36

Magnesium sulfate is an unfit anticonvulsant in eclampsia (Luan) (Letter); (Sibai) (Reply). 1992;166:1588

Antigens

Derivation of new mathematic formulas for determining whether a D-positive father is heterozygous or homozygous for the D antigen (Kanter). 1992;166:61-3

Human monoclonal antibody recognizing an antigen associated with ovarian and other adenocarcinomas (Smith et al). 1992;166:634-45

Preeclampsia, von Willebrand factor antigen, and endothelial cells (Blann) (Letter); (Taylor et al) (Reply). 1992;166:769-70

Antigens, tumor-associated, carbohydrate

The clinical significance of thrombocytosis in women presenting with a pelvic mass (Chalas et al). 1992;166:974-7

Antineoplastic agents

Anticancer drugs during pregnancy: Are we able to discard them? (Kim et al) (Letter); (van der Zee et al) (Reply). 1992;166:265-6

Antinuclear antibody; *see* **Antibodies, antinuclear**

Antiphospholipid antibody; *see* **Autoantibodies**

Aorta

Intracerebral, aortic, and umbilical artery flow velocity

Aorta—cont'd
waveforms in the late-first-trimester fetus (Wladimiroff et al). 1992;166:46-9
Apolipoproteins
Lipid and apolipoprotein abnormalities in hirsute women. I. The association with insulin resistance (Wild et al). 1992;166:1191-7
Appendicitis
Abruptio placentae associated with perforated appendicitis and generalized peritonitis (Yaron et al). 1992;166:14-5
Arginine
Nω-Nitro-L-arginine, and inhibitor of nitric oxide synthesis, increases blood pressure in rats and reverses the pregnancy-induced refractoriness to vasopressor agents (Molnár and Hertelendy). 1992;166:1560-7
Ascariasis
Nematode infections: Is it wise to withhold medical treatment during pregnancy? I. Biliary complications (Villar L. and Sibai). 1992;166:549-50
Ascitic fluid
The effect of preovulatory peritoneal fluid from cases of endometriosis on murine in vitro fertilization, embryo development, oviduct transport, and implantation (Dodds et al). 1992;166:219-24
Substance P in peritoneal fluid (Sanfilippo et al). 1992;166:155-9
Asphyxia
Meconium aspiration syndrome: reflections on a murky subject (Katz and Bowes). 1992;166:171-83 (Curr. dev.)
The physiologic mechanisms of variable decelerations (Ball and Parer). 1992;166:1683-9
Role of prostaglandins in the metabolic responses of the fetus to hypoxia (Hooper et al). 1992;166:1568-75
Atrial natriuretic peptide; *see* **Natriuretic peptides, atrial**
Attitude
Animals and ethics: how society's attitudes have changed (Fritzsche) (Letter); (Maharry) (Reply). 1992;166:1312-3
Attitudes toward reproduction in a nonpatient population (Wikman et al). 1992;166:121-6
Auscultation
The accuracy of auscultatory detection of fetal cardiac decelerations: a computer simulation (Schifrin et al). 1992;166:566-76
Details of electronic fetal monitoring randomized control trials (Schifrin) (Letter); (Ellison) (Reply). 1992;166:1308-9
Autoantibodies
Interlaboratory variation in antiphospholipid antibody testing (Peaceman et al). 1992;166:1780-7
Repeated fetal losses associated with antiphospholipid antibodies: a collaborative randomized trial comparing prednisone with low-dose heparin treatment (Cowchock et al). 1992;166:1318-23
Autoimmunity
Reproductive outcome in women with recurrent spontaneous abortions of alloimmune and autoimmune causes: preconception versus postconception treatment (Kwak et al). 1992;166:1787-98

B

Backache
An integrated therapy for peripartum pelvic instability: a study of the biomechanical effects of pelvic belts (Vleeming et al). 1992;166:1243-7
Bacteria
Characteristics of three vaginal flora patterns assessed by Gram stain among pregnant women (Hillier et al). 1992;166:938-44
Bacterial vaginosis; *see* **Vaginitis**
Benzo(a)pyrene
The effect of benzo(a)pyrene on murine ovarian and corpora lutea volumes (Miller et al). 1992;166:1535-41
17Beta-estradiol; *see* **Estradiol**
Beta-human chorionic gonadotropin; *see* **Gonadotropins, chorionic**
Betamethasone
Effects of antenatal thyrotropin-releasing hormone, antenatal corticosteroids, and postnatal ventilation on surfactant mobilization in premature rabbits (Seidner et al). 1992;166:1551-9
A randomized, placebo-controlled trial of betamethasone for the prevention of respiratory distress syndrome at 24 to 28 weeks' gestation (Garite et al). 1992;166:646-51
Bicycle exercise test; *see* **Exercise test**
Biliary tract
Nematode infections: Is it wise to withhold medical treatment during pregnancy? I. Biliary complications (Villar L. and Sibai). 1992;166:549-50
Bilirubin
Human fetal bilirubin levels and fetal hemolytic disease (Weiner). 1992;166:1449-54
Binding sites
Changes in human platelet angiotensin II binding sites associated with early pregnancy (Baker et al). 1992;166:255-6
The presence of platelet-activating factor binding sites in human myometrium and their role in uterine contraction (Zhu et al). 1992;166:1222-7
Bioavailability; *see* **Biological availability**
Biological availability
Bioavailability of nafarelin in healthy volunteers (Chaplin). 1992;166:762-5
Postmenopausal steroid replacement with micronized dehydroepiandrosterone: preliminary oral bioavailability and dose proportionality studies (Buster et al). 1992;166:1163-70
Biophysics
Comprehensive fetal assessment with three ultrasonographic characteristics (James et al). 1992;166:1486-95
Fetal biophysical and umbilical cord gases (Modanlou) (Letter); (Vintzileos et al) (Reply). 1992;166:1589
Population differences of fetal biophysical and behavioral characteristics (Johnson et al). 1992;166:138-42
Biopsy
Hysteroscopic myometrial biopsy: its use in diagnosing adenomyosis and its clinical application (McCausland). 1992;166:1619-28
Prevalence of out-of-phase endometrial biopsy specimens (Peters et al). 1992;166:1738-46
Birth; *see* **Delivery**
Birth defects; *see* **Abnormalities**
Birth injuries
Brachial plexus palsy: an old problem revisited (Jennett et al). 1992;166:1673-7
Birth weight
Efficacy of the fetal-pelvic index in nulliparous women at high risk for fetal-pelvic disproportion (Morgan and Thurnau). 1992;166:810-4

Neonatal morbidity according to gestational age and birth weight from five tertiary care centers in the United States, 1983 through 1986 (Robertson et al). 1992;166:1629-45

Blastocyst

Inhibition of preimplantation mouse embryo development by isoflurane (Warren et al). 1992;166:693-8

Blood

Magnetic cell sorting and the transferrin receptor as potential means of prenatal diagnosis from maternal blood (Gänshirt-Ahlert et al). 1992;166:1350-5

Blood, analysis

Analysis of peripheral blood of pregnant women for the presence of fetal Y chromosome–specific ZFY gene deoxyribonucleic acid sequences (Kao et al). 1992;166:1013-9

Blood circulation

Doppler ultrasonographic features of the developing placental circulation: correlation with anatomic findings (Jauniaux et al). 1992;166:585-7

Blood flow velocity

Inferior vena cava flow velocity waveforms in appropriate- and small-for-gestational-age fetuses (Rizzo et al). 1992;166:1271-80

Intracerebral, aortic, and umbilical artery flow velocity waveforms in the late-first-trimester fetus (Wladimiroff et al). 1992;166:46-9

Middle cerebral artery flow velocity waveforms in normal and small-for-gestational-age fetuses (Mari and Deter). 1992;166:1262-70

Normal fetal Doppler inferior vena cava, transtricuspid, and umbilical artery flow velocity waveforms between 11 and 16 weeks' gestation (Wladimiroff et al). 1992;166:921-4

Umbilical artery flow velocity after vibratory acoustic stimulation (Nakamura et al) (Letter); (Gagnon et al) (Reply). 1992;166:1865-6

Uterine and umbilical flow velocity waveforms in normotensive and hypertensive subjects during the angiotensin II sensitivity test (Erkkola and Pirhonen). 1992;166:910-6

Blood gas analysis

The effect of fetal sepsis on umbilical cord gases (Meyer et al). 1992;166:612-7

Fetal biophysical and umbilical cord gases (Modanlou) (Letter); (Vintzileos et al) (Reply). 1992;166:1589

Long-term acid-base measurements in the fetal and maternal baboon (Daniel et al). 1992;166:707-12

Vaginal Po_2 in healthy women and in women infected with *Trichomonas vaginalis*: potential implications for metronidazole therapy (Rashad et al). 1992;166:620-4

Venous drainage of the human uterus: respiratory gas studies in normal and fetal growth-retarded pregnancies (Pardi et al). 1992;166:699-706

Blood grouping and crossmatching

Chorionic villus sampling for fetal Rh typing: clinical implications (Kickler et al). 1992;166:1407-11

Blood platelet disorders

May-Hegglin anomaly: a rare case of maternal thrombocytopenia in pregnancy (Chatwani et al). 1992;166:143-4

Blood platelets

The blood pressure response to infusions of angiotensin II during normal pregnancy: relation to plasma angiotensin II concentration, serum progesterone level, and mean platelet volume (Ito et al). 1992;166:1249-53

Changes in human platelet angiotensin II binding sites associated with early pregnancy (Baker et al). 1992;166:255-6

Blood pressure

Arterial pressure response to maximal isometric exercise in pregnant women (Lotgering et al). 1992;166:538-42

The blood pressure response to infusions of angiotensin II during normal pregnancy: relation to plasma angiotensin II concentration, serum progesterone level, and mean platelet volume (Ito et al). 1992;166:1249-53

Describing and interpreting 24-hour blood pressure patterns in physiologic pregnancy (Cugini et al). 1992;166:54-60

The Diabetes in Early Pregnancy Study: changes in cholesterol, triglycerides, body weight, and blood pressure (Peterson et al). 1992;166:513-8

Maternal and fetal cardiovascular responses to strenuous bicycle exercise (van Doorn et al). 1992;166:854-9

More on early detection of preeclampsia (Ales) (Letter); (Sibai) (Reply). 1992;166:1306-8

Nω-Nitro-L-arginine, and inhibitor of nitric oxide synthesis, increases blood pressure in rats and reverses the pregnancy-induced refractoriness to vasopressor agents (Molnár and Hertelendy). 1992;166:1560-7

Blood transfusion, intrauterine

Acute posttraumatic fetal anemia treated with fetal intravascular transfusion (Del Valle et al). 1992;166:127-9

Alloimmune thrombocytopenia may be associated with systemic disease (Kay et al). 1992;166:110-1

Severe anti-C hemolytic disease of the newborn (Bowman et al). 1992;166:1239-43

Blood vessels

Platelet activation and vascular damage in gestational hypertension (Ballegeer et al). 1992;166:629-33

Prostaglandin- or endothelium-mediated vasodilation is not involved in the blunted responses of blood vessels to vasoconstrictors in pregnant rats (St-Louis and Sicotte). 1992;166:684-92

Body fluids

Human vaginal leukocytes and the effects of vaginal fluid on lymphocyte and macrophage defense functions (Hill and Anderson). 1992;166:720-6

Transvaginal ultrasonographic quantitative assessment of accumulated cul-de-sac fluid (Rosen et al). 1992;166:542-4

Body weight

The Diabetes in Early Pregnancy Study: changes in cholesterol, triglycerides, body weight, and blood pressure (Peterson et al). 1992;166:513-8

Bone density

The effect of sex steroids on the skeleton in premenopausal women (Lindsay). 1992;166:1993-6

Low-dosage micronized 17β-estradiol prevents bone loss in postmenopausal women (Ettinger et al). 1992;166:479-88

Books

Books received. 1992;166:1026-7

Brachial plexus

Brachial plexus palsy: an old problem revisited (Jennett et al). 1992;166:1673-7

Brain, blood supply

Changes in human fetal cerebral hemoglobin concentration and oxygenation during labor measured by near-infrared spectroscopy (Peebles et al). 1992;166:1369-73

Breast neoplasms

The benefits and risks of hormone replacement therapy: an epidemiologic overview (Harlap). 1992;166:1986-92

Breast neoplasms—cont'd
Functional analysis of a mutant estrogen receptor isolated from T47Dco breast cancer cells (Leslie et al). 1992;166:1053-61
Maternal and fetal outcome after breast cancer in pregnancy (Zemlickis et al). 1992;166:781-7
The safety of oral contraceptives: epidemiologic insights from the first 30 years (Grimes). 1992;166:1950-4
Breech presentation
Breech extraction of low-birth-weight second twins: Can cesarean section be justified? (Davison et al). 1992;166:497-502
The frequency of breech presentation by gestational age at birth: a large population-based study (Hickok et al). 1992;166:851-2
British empire; *see* **Great Britain**
8-Bromo-cyclic adenosine monophosphate; *see* **Adenosine cyclic monophosphate**
Bulky-barrel carcinoma; *see* **Carcinoma**
Burns
Comparison of thermal injury zones in loop electrical and laser cervical excisional conization (Baggish et al). 1992;166:545-8
Buserelin acetate
Buserelin acetate versus expectant management in the treatment of infertility associated with minimal or mild endometriosis: a randomized clinical trial (Fedele et al). 1992;166:1345-50

C

C-fos; *see* **Proto-oncogenes**
CA-125; *see* **Antigens, tumor-associated, carbohydrate**
Calcium
Low-dosage micronized 17β-estradiol prevents bone loss in postmenopausal women (Ettinger et al). 1992;166:479-88
Calcium metabolism disorders
Abnormal 1,25-dihydroxyvitamin D metabolism in preeclampsia (August et al). 1992;166:1295-9
Cancer; *see* **Neoplasms**
Candida
Cellular immunity of patients with recurrent or refractory vulvovaginal moniliasis (Fong et al). 1992;166:887-90
Carbohydrates, metabolism
The effect of continuous subdermal levonorgestrel (Norplant) on carbohydrate metabolism (Konje et al). 1992;166:15-9
Effects of β-hydroxybutyrate infusion on hind limb metabolism in fetal sheep (Harding et al). 1992;166:671-6
Carcinoma
Accuracy of frozen-section diagnosis at surgery in clinical state I and II endometrial carcinoma (Shim et al). 1992;166:1335-8
Advanced epithelial ovarian carcinoma: long-term survival experience at the community hospital (Unzelman). 1992;166:1663-72
Both 17β-estradiol and tamoxifen induce c-*fos* messenger ribonucleic acid expression in human endometrial carcinoma grown in nude mice (Sakakibara et al). 1992;166:206-12
The cavitational ultrasonic surgical aspirator for cytoreduction in advanced ovarian cancer (Rose). 1992;166:843-6
Diathermy loop excision in the management of cervical intraepithelial neoplasia: diagnosis and treatment in one procedure (Keijser et al). 1992;166:1281-7
In situ and invasive vulvar cancer incidence trends (1973 to 1987) (Sturgeon et al). 1992;166:1482-5
Immunohistochemical detection of the multi-drug-resistance marker P-glycoprotein in uterine cervical carcinomas and normal cervical tissue (Schneider et al). 1992;166:825-9
Laparoscopic radical hysterectomy with paraaortic and pelvic node dissection (Nezhat et al). 1992;166:864-5
Meta-analysis of surgery in advanced ovarian carcinoma: Is maximum cytoreductive surgery an independent determinant of prognosis? (Hunter et al). 1992;166:504-11
Ovarian carcinoma of low malignant potential, infertility, and induction of ovulation: Is there a link? (Goldberg and Runowicz). 1992;166:853-4
Ovarian metastases in stage IB carcinoma of the cervix: a Gynecologic Oncology Group study (Sutton et al). 1992;166:50-3
Patterns of failure of bulky-barrel carcinomas of the cervix (Coleman et al). 1992;166:916-20
Radical hysterectomy in the elderly patient: analysis of morbidity (Fuchtner et al). 1992;166:593-7
Upper vaginectomy for in situ and occult, superficially invasive carcinoma of the vagina (Hoffman et al). 1992;166:30-3
Carcinoma, squamous cell
Comparison of adenocarcinoma and squamous cell carcinoma of the uterine cervix: a population-based epidemiologic study (Anton-Culver et al). 1992;166:1507-14
A comprehensive program for cervical cancer detection and management (Benedet et al). 1992;166:1254-9
In situ and invasive vulvar cancer incidence trends (1973 to 1987) (Sturgeon et al). 1992;166:1482-5
Cardiac output
Effects of chronic maternal anemia on systemic and uteroplacental oxygenation in near-term pregnant sheep (Delpapa et al). 1992;166:1007-12
Cardiotonic agents
The maternal and fetal effects of milrinone and dopamine in normotensive pregnant ewes (Santos et al). 1992;166:257-62
Cardiovascular disease; *see* **Heart diseases**
Cardiovascular diseases
The benefits and risks of hormone replacement therapy: an epidemiologic overview (Harlap). 1992;166:1986-92
Clinical and metabolic considerations of long-term oral contraceptive use (Godsland et al). 1992;166:1955-63
Norgestimate: a clinical overview of a new progestin (Bringer). 1992;166:1969-77
Catecholamines
Catecholamines modulate epidermal growth factor–induced prostaglandin E_2 production in amnion-like (WISH) cells by means of a cyclic adenosine monophosphate–dependent pathway (Su et al). 1992;166:236-41
Change in electrocardiogram T-wave amplitude during umbilical cord compression is predictive of fetal condition in sheep (Watanabe et al). 1992;166:246-55
Elevated plasma Met-enkephalin levels in the human newborn are a poor indicator of perinatal stress (Martinez et al). 1992;166:1429-35
Cavitational ultrasonic surgical aspirator; *see* **Surgery, operative**
Cell separation
Magnetic cell sorting and the transferrin receptor as potential means of prenatal diagnosis from maternal blood (Gänshirt-Ahlert et al). 1992;166:1350-5

Cellular immunity; *see* **Immunity, cellular**
Cellulose, oxidized
Comparison of the peritoneal cells elicited by oxidized regenerated cellulose (Interceed) and expanded polytetrafluoroethylene (Gore-Tex Surgical Membrane) in a murine model (Haney and Doty). 1992;166:1137-49
Central Association of Obstetricians and Gynecologists
Transactions of the fifty-ninth annual meeting of the Central Association of Obstetricians and Gynecologists. 1992;166:1712-62
Cerebral arteries
Intracerebral, aortic, and umbilical artery flow velocity waveforms in the late-first-trimester fetus (Wladimiroff et al). 1992;166:46-9
Middle cerebral artery flow velocity waveforms in normal and small-for-gestational-age fetuses (Mari and Deter). 1992;166:1262-70
Cerebral hemoglobin; *see* **Hemoglobins**
Cervical ripening; *see* **Labor stage, first**
Cervix
Cervical cytology: a randomized comparison of four sampling methods (McCord et al). 1992;166:1772-9
Comparison of thermal injury zones in loop electrical and laser cervical excisional conization (Baggish et al). 1992;166:545-8
Origin of cervical collagenase during parturition (Osmers et al). 1992;166:1455-60
Cervix diseases
Cervical stenosis in pregnancy: a complication of cryotherapy in diethylstilbestrol-exposed women (Kalstone). 1992;166:502-3
Cervix dysplasia
Oral folic acid supplementation for cervical dysplasia: a clinical intervention trial (Butterworth et al). 1992;166:803-9
Cervix incompetence
Diagnosis of cervical change in pregnancy by means of transvaginal ultrasonography (Joffe et al). 1992;166:896-900
Cervix neoplasms
Comparison of adenocarcinoma and squamous cell carcinoma of the uterine cervix: a population-based epidemiologic study (Anton-Culver et al). 1992;166:1507-14
A comprehensive program for cervical cancer detection and management (Benedet et al). 1992;166:1254-9
Diathermy loop excision in the management of cervical intraepithelial neoplasia: diagnosis and treatment in one procedure (Keijser et al). 1992;166:1281-7
Epidermal growth factor receptor expression in cervical intraepithelial neoplasia (Mittal). 1992;166:1593 (Letter)
Immunohistochemical detection of the multi-drug-resistance marker P-glycoprotein in uterine cervical carcinomas and normal cervical tissue (Schneider et al). 1992;166:825-9
Laparoscopic radical hysterectomy with paraaortic and pelvic node dissection (Nezhat et al). 1992;166:864-5
Ovarian metastases in stage IB carcinoma of the cervix: a Gynecologic Oncology Group study (Sutton et al). 1992;166:50-3
Patterns of failure of bulky-barrel carcinomas of the cervix (Coleman et al). 1992;166:916-20
Radical hysterectomy for treatment of cervical cancer: a prospective study of two methods of closed-suction drainage (Barton et al). 1992;166:533-7
Radical hysterectomy in the elderly patient: analysis of morbidity (Fuchtner et al). 1992;166:593-7
The utility of immunocytochemistry in invasive adenocarcinoma of the cervix (Tamimi et al). 1992;166:1655-62
Cesarean section
Acute childbirth morbidity: its measurement using hospital charges (Hage et al). 1992;166:1853-62
Benefits of cesarean section stapling device understated? (Martens). 1992;166:266-7 (Letter)
Breech extraction of low-birth-weight second twins: Can cesarean section be justified? (Davison et al). 1992;166:497-502
The effect of cesarean section on intraventricular hemorrhage in the preterm infant (Anderson et al). 1992;166:1091-101
First successful cesarean section in the British empire (Miller). 1992;166:269 (Letter)
The Green Bay cesarean section study. II. The physician factor as a determinant of cesarean birth rates for failed labor (DeMott and Sandmire). 1992;166:1799-810
The uterine stapling device for cesarean section: a positive view (Pelosi and Pelosi) (Letter); (Villeneuve et al) (Reply). 1992;166:267-8
The Zavanelli maneuver applied to locked twins (Swartjes et al). 1992;166:532
Chemotherapy; *see* **Drug therapy**
Child
Acute genital injury in the prepubertal girl (Pokorny et al). 1992;166:1461-6
Child abuse, sexual
Acute genital injury in the prepubertal girl (Pokorny et al). 1992;166:1461-6
Childbirth; *see* **Labor**
Cholesterol
Comparison of transdermal and oral estrogen/progestin replacement therapy: effects on serum lipids and lipoproteins (Crook et al). 1992;166:950-5
The Diabetes in Early Pregnancy Study: changes in cholesterol, triglycerides, body weight, and blood pressure (Peterson et al). 1992;166:513-8
Prolonged effects of a novel, low-dosage continuous progestin–cyclic estrogen replacement program in postmenopausal women (Plunkett and Wolfe). 1992;166:117-21
Chorioamnionitis
Endothelin-1 and endothelin-2 levels are increased in the amniotic fluid of women with preterm labor and microbial invasion of the amniotic cavity (Romero et al). 1992;166:95-9
Eradication of *Ureaplasma urealyticum* from the amniotic fluid with transplacental antibiotic treatment (Romero et al). 1992;166:618-20
Infection and labor. VII. Microbial invasion of the amniotic cavity in spontaneous rupture of membranes at term (Romero et al). 1992;166:129-33
The relationship between acute inflammatory lesions of the preterm placenta and amniotic fluid microbiology (Romero et al). 1992;166:1382-8
A review of premature birth and subclinical infection (Gibbs et al). 1992;166:1515-28 (Curr. dev.)
Chorioangioma; *see* **Hemangioma**
Chorionic villi sampling
Chorionic villus sampling for fetal Rh typing: clinical implications (Kickler et al). 1992;166:1407-11
Transabdominal chorionic villus sampling: a modified freehand ultrasonographically guided technique (Hill and Laifer). 1992;166:512

Choroid plexus
Bilateral choroid plexus cysts in trisomy 21 (Rotmensch et al). 1992;166:591-2
Chromosome abnormalities
Bilateral choroid plexus cysts in trisomy 21 (Rotmensch et al). 1992;166:591-2
Prenatal diagnosis of autosomal recessive polycystic kidney disease: variable outcome within one family (Barth et al). 1992;166:560-7
Clinical opinion
Clinical opinion. 1992;166:1-3, 775-80
Clomiphene
Steroids receptors in the endometrium during clomiphene citrate treatment (Shabib and Pittrof) (Letter); (Fritz) (Reply). 1992;166:1866-7
Collagen
The function of elevated plasma fibronectin in preeclampsia (Brubaker et al). 1992;166:526-31
Collagenase
Origin of cervical collagenase during parturition (Osmers et al). 1992;166:1455-60
College of American Pathologists
Examination of placentas by pathologists (Altshuler). 1992;166:1312 (Letter)
Colorimetry
Prediction of respiratory distress syndrome by a new colorimetric assay (Almog et al). 1992;166:1827-34
Colposcopy
Colposcopy to establish physical findings in rape victims (Slaughter and Brown). 1992;166:83-6
A comprehensive program for cervical cancer detection and management (Benedet et al) 1992;166:1254-9
Compliance; *see* **Patient compliance**
Computer simulation
The accuracy of auscultatory detection of fetal cardiac decelerations: a computer simulation (Schifrin et al). 1992;166:566-76
Conception; *see* **Fertilization**
Congenital malformations; *see* **Abnormalities**
Congenital myotonic dystrophy; *see* **Myotonia atrophica**
Contraceptives
Contraceptive prevalence, reproductive health, and international morality (Diczfalusy). 1992;166:1037-43
The effect of continuous subdermal levonorgestrel (Norplant) on carbohydrate metabolism (Konje et al). 1992;166:15-9
Rates and outcomes of planned pregnancy after use of Norplant capsules, Norplant II rods, or levonorgestrel-releasing or copper TCu 380Ag intrauterine contraceptive devices (Sivin et al). 1992;166:1208-13
Contraceptives, oral
Clinical and metabolic considerations of long-term oral contraceptive use (Godsland et al). 1992;166:1955-63
Contraceptive compliance with a levonorgestrel triphasic and a norethindrone monophasic oral contraceptive in adolescent patients (Woods et al). 1992;166:901-7
Dysmenorrhea and use of oral contraceptives in adolescent women attending a family planning clinic (Robinson et al). 1992;166:578-83
The efficacy and tolerability of norgestimate/ethinyl estradiol (250 μg of norgestimate/35 μg of ethinyl estradiol): results of an open, multicenter study of 59,701 women (Runnebaum et al). 1992;166:1963-8
Norgestimate: a clinical overview of a new progestin (Bringer). 1992;166:1969-77
Oral contraceptive type and functional ovarian cysts (Lanes et al). 1992;166:956-61
The safety of oral contraceptives: epidemiologic insights from the first 30 years (Grimes). 1992;166:1950-4
Steroids from menarche to menopause: introduction (Mishell). 1992;166:1949
Copper intrauterine devices; *see* **Intrauterine devices, copper**
Cord blood; *see* **Fetal blood**
Cordocentesis; *see* **Fetal blood**
Corpus luteum
The effect of benzo(a)pyrene on murine ovarian and corpora lutea volumes (Miller et al). 1992;166:1535-41
Corrections
Fetal maternal laryngeal papillomatosis in pregnancy: a case report (Helmrich et al) (1992;166:524-5). 1992;166:1313
Increased progesterone concentrations are necessary to suppress interleukin-2–activated human mononuclear cell cytotoxicity (Feinberg et al) (1991;165:1872-6). 1992;166:1313
Relationship between biophysical activities and umbilical cord blood gas values (Vintzileos et al) (1991;165:707-13). 1992;166:1313
Correspondence
Letters. 1992;166:263-9, 766-71, 1020-5, 1306-13, 1588-93, 1863-8
Corticotropin-releasing hormone
Elevated maternal plasma corticotropin-releasing hormone levels in pregnancies complicated by preterm labor (Warren et al). 1992;166:1198-207
Cortisol; *see* **Hydrocortisone**
Cost benefit analysis
Increasing use of gynecologic ultrasonography (Goldstein) (Letter); (Willson) (Reply). 1992;166:1310-1
Crown-rump length dating; *see* **Gestational age**
Cryosurgery
Cervical stenosis in pregnancy: a complication of cryotherapy in diethylstilbestrol-exposed women (Kalstone). 1992;166:502-3
Current development
Current development. 1992;166:171-83, 1515-28
Cystadenoma
Giant ovarian cyst: case report (Zamora-Garza et al). 1992;166:1247-8
Cystitis
Eosinophilic cystitis during pregnancy (Chamberlin). 1992;166:28-9
Cystourethropexy
Modified retropubic cystourethropexy II (Goodno and Powers). 1992;166:1678-82
Cysts
Bilateral choroid plexus cysts in trisomy 21 (Rotmensch et al). 1992;166:591-2
Cytochrome P-450
Rapid identification of deoxyribonucleic acid sequence differences in cytochrome P-450 21-hydroxylase (CYP21) genes with denaturing gradient gel blots (Reindollar et al). 1992;166:184-91
Cytology
A comprehensive program for cervical cancer detection and management (Benedet et al). 1992;166:1254-9
Cytomegaloviruses
Prenatal diagnosis of fetal cytomegalovirus infection (Lamy et al). 1992;166:91-4
What is the prognosis for congenital cytomegalovirus infection? (Binder). 1992;166:1591 (Letter)

Cytoreduction; *see* **Surgery, operative**

D

D antigen; *see* **Antigens**
Debridement
Necrotizing fasciitis of the vulva (Stephenson et al). 1992;166:1324-7
Decidua
Influence of labor and oxytocin on in vitro leukotriene release by human fetal membranes and uterine decidua at term gestation (Pasetto et al). 1992;166:1500-6
Dehydroepiandrosterone
Postmenopausal steroid replacement with micronized dehydroepiandrosterone: preliminary oral bioavailability and dose proportionality studies (Buster et al). 1992;166:1163-70
Delivery
Actocardiotocographic monitoring of triplets during vaginal delivery (van Eyck and Arabin). 1992;166:1293-4
Brachial plexus palsy: an old problem revisited (Jennett et al). 1992;166:1673-7
Vaginal birth after cesarean delivery: Are there useful and valid predictors of success or failure? (Pickhardt et al). 1992;166:1811-9
The Zavanelli maneuver applied to locked twins (Swartjes et al). 1992;166:532
Denaturing gradient gel electrophoresis; *see* **Electrophoresis**
Deoxyribonucleic acid; *see* **DNA**
Department chairmen; *see* **Medical staff**
Depression
Depressive symptoms in women in the 6 months after miscarriage (Neugebauer et al). 1992;166:104-9
Dextrans
Documentation of high-molecular-weight dextran (Hyskon) solution entering the serum during hysteroscopy (Mangar). 1992;166:771 (Letter)
Diabetes mellitus
Fetal polycythemia and thrombocytopenia in pregnancies complicated by maternal diabetes mellitus (Salvesen et al). 1992;166:1287-92
Necrotizing fasciitis of the vulva (Stephenson et al). 1992;166:1324-7
Diabetes mellitus, insulin-dependent
Impairment of counterregulatory hormone responses to hypoglycemia in pregnant women with insulin-dependent diabetes mellitus (Diamond et al). 1992;166:70-7
Infertility and pregnancy outcome in an unselected group of women with insulin-dependent diabetes mellitus (Kjaer et al). 1992;166:1412-8
Progression of diabetic retinopathy in pregnancy: association with hypertension in pregnancy (Rosenn et al). 1992;166:1214-8
Diabetic retinopathy
Progression of diabetic retinopathy in pregnancy: association with hypertension in pregnancy (Rosenn et al). 1992;166:1214-8
Diagnosis
Examination of placentas by pathologists (Altshuler). 1992;166:1312 (Letter)
Diaphragmatic hernia; *see* **Hernia, diaphragmatic**
Diathermy loop excision; *see* **Electrocoagulation**
Diet therapy
Maternal phenylketonuria collaborative study, obstetric aspects and outcome: the first 6 years (Platt et al). 1992;166:1150-62
Diethylstilbestrol
Cervical stenosis in pregnancy: a complication of cryotherapy in diethylstilbestrol-exposed women (Kalstone). 1992;166:502-3
Digoxin
Treatment of fetal supraventricular tachycardia with flecainide acetate after digoxin failure (Mills) (Letter); (Kofinas) (Reply). 1992;166:1863
Dihydroxycholecalciferols
Abnormal 1,25-dihydroxyvitamin D metabolism in preeclampsia (August et al). 1992;166:1295-9
Dihydroxyvitamin D; *see* **Dihydroxycholecalciferols**
Dilatation
Origin of cervical collagenase during parturition (Osmers et al). 1992;166:1455-60
Dinoprostone
Catecholamines modulate epidermal growth factor–induced prostaglandin E_2 production in amnion-like (WISH) cells by means of a cyclic adenosine monophosphate–dependent pathway (Su et al). 1992;166:236-41
Effects of platelet-activating factor on prostaglandin E_2 production by intact fetal membranes (Morris et al). 1992;166:1228-31
Influence of terbutaline on ovine uterine response to prostaglandin E_2 challenge (Reid et al). 1992;166:231-5
Prostaglandin E_2 for induction of labor in patients with premature rupture of membranes at term (Ray and Garite). 1992;166:836-43
A randomized trial of prostaglandin E_2 in a controlled-release vaginal pessary for cervical ripening at term (Witter et al). 1992;166:830-4
DNA
Analysis of peripheral blood of pregnant women for the presence of fetal Y chromosome–specific ZFY gene deoxyribonucleic acid sequences (Kao et al). 1992;166:1013-9
Rapid identification of deoxyribonucleic acid sequence differences in cytochrome P-450 21-hydroxylase (CYP21) genes with denaturing gradient gel blots (Reindollar et al). 1992;166:184-91
DNA fingerprinting
Triplet pregnancy involving complete hydatidiform mole and two fetuses: genetic analysis by deoxyribonucleic acid fingerprint (Azuma et al). 1992;166:664-7
DNA mutational analysis
Deoxyribonucleic acid analysis by flow cytometry of uterine leiomyosarcomas and smooth muscle tumors of uncertain malignant potential (Peters et al). 1992;166:1646-54
Functional analysis of a mutant estrogen receptor isolated from T47Dco breast cancer cells (Leslie et al). 1992;166:1053-61
Donor insemination; *see* **Insemination, artificial**
Dopamine
The maternal and fetal effects of milrinone and dopamine in normotensive pregnant ewes (Santos et al). 1992;166:257-62
Doppler ultrasonography; *see* **Ultrasonography**
Doppler velocimeters; *see* **Flowmeters**
Dose-response relationship, drug
Factors affecting the dose response to oxytocin for labor stimulation (Satin et al). 1992;166:1260-1
Postmenopausal steroid replacement with micronized dehydroepiandrosterone: preliminary oral bioavailability and dose proportionality studies (Buster et al). 1992;166:1163-70

Down syndrome
Fetal humeral length to detect Down syndrome (Rotmensch et al). 1992;166:1330-4
Ultrasonographic dating of pregnancy causes significant errors in Down syndrome risk assessment that may be minimized by use of biparietal diameter–based means (Reynolds et al). 1992;166:872-7
Ultrasonographic screening for trisomy 21 (Bernstein) (Letter); (Lockwood et al) (Reply). 1992;166:1591
Drainage, suction
Radical hysterectomy for treatment of cervical cancer: a prospective study of two methods of closed-suction drainage (Barton et al). 1992;166:533-7
Drug abuse; *see* **Substance abuse**
Drug screening
Routine urine drug screening at the first prenatal visit (Colmorgen et al). 1992;166:583-90
Drug therapy
Advanced epithelial ovarian carcinoma: long-term survival experience at the community hospital (Unzelman). 1992;166:1663-72
Maternal and fetal outcome after breast cancer in pregnancy (Zemlickis et al). 1992;166:781-7
Meta-analysis of surgery in advanced ovarian carcinoma: Is maximum cytoreductive surgery an independent determinant of prognosis? (Hunter et al). 1992;166:504-11
Dysmenorrhea
Dysmenorrhea and use of oral contraceptives in adolescent women attending a family planning clinic (Robinson et al). 1992;166:578-83
Dystocia
Brachial plexus palsy: an old problem revisited (Jennett et al). 1992;166:1673-7
Does oxytocin augmentation increase perinatal risk in primigravid labor? (Cahill et al). 1992;166:847-50

E

Early menopause; *see* **Menopause, premature**
Early pregnancy; *see* **Pregnancy trimester, first**
Echocardiography
Fetal echocardiography: accuracy and limitations in a population at high and low risk for heart defects (Bromley et al). 1992;166:1473-81
Eclampsia
Anticonvulsant effects of magnesium sulfate on hippocampal seizures: therapeutic implications in preeclampsia-eclampsia (Cotton et al). 1992;166:1127-36
Eclampsia. VII. Pregnancy outcome after eclampsia and long-term prognosis (Sibai et al). 1992;166:1757-63
Magnesium sulfate is an unfit anticonvulsant in eclampsia (Luan) (Letter); (Sibai) (Reply). 1992;166:1588
Main clinical types and subtypes of eclampsia (López-Llera). 1992;166:4-9
Ectopic pregnancy; *see* **Pregnancy, ectopic**
Editorial
Summary of analysis of published articles. 1992;166:773-4
Education
Resident attrition in obstetrics and gynecology (Seltzer et al). 1992;166:1315-7
Training obstetric and family practice residents to give smoking cessation advice during prenatal care (Secker-Walker et al). 1992;166:1356-63
Efficiency
Receiver-operator characteristic, efficiency analysis, and predictive value of serum progesterone concentration as a test for abnormal gestations (Cowan et al). 1992;166:1729-37
Eicosanoic acids
The mechanisms of preterm labor: common genital tract pathogens do not metabolize arachidonic acid to prostaglandins or to other eicosanoids (Bennett and Elder). 1992;166:1541-5
Eicosanoids
The mechanisms of preterm labor: common genital tract pathogens do not metabolize arachidonic acid to prostaglandins or to other eicosanoids (Bennett and Elder). 1992;166:1541-5
Electrocardiography
Change in electrocardiogram T-wave amplitude during umbilical cord compression is predictive of fetal condition in sheep (Watanabe et al). 1992;166:246-55
Maternal and fetal cardiovascular responses to strenuous bicycle exercise (van Doorn et al). 1992;166:854-9
Electrocoagulation
Diathermy loop excision in the management of cervical intraepithelial neoplasia: diagnosis and treatment in one procedure (Keijser et al). 1992;166:1281-7
Electrophoresis
Rapid identification of deoxyribonucleic acid sequence differences in cytochrome P-450 21-hydroxylase (CYP21) genes with denaturing gradient gel blots (Reindollar et al). 1992;166:184-91
Electrosurgery
Comparison of thermal injury zones in loop electrical and laser cervical excisional conization (Baggish et al). 1992;166:545-8
Embolization, therapeutic
Angiographic embolization in the management of hemorrhagic complications of pregnancy (Gilbert et al). 1992;166:495-7
Embryo
Evidence of embryo- and trophoblast-toxic cellular immune response(s) in women with recurrent spontaneous abortion (Hill et al). 1992;166:1044-52
Embryo development; *see* **Fetal development**
Embryo transfer
Pelvic abscess complicating transcervical embryo transfer (Sauer and Paulson). 1992;166:148-9
Selection bias in in vitro fertilization programs (Hershlag et al). 1992;166:1-3 (Clin. opinion)
Embryoscopy
Embryoscopy: a closer look at first-trimester diagnosis and treatment (Reece et al). 1992;166:775-80 (Clin. opinion)
Emergency service, hospital
Emergency room use of transvaginal ultrasonography by obstetrics and gynecology residents (Timor-Tritsch et al). 1992;166:866-72
Endometrial neoplasms; *see* **Uterine neoplasms**
Endometriosis
Buserelin acetate versus expectant management in the treatment of infertility associated with minimal or mild endometriosis: a randomized clinical trial (Fedele et al). 1992;166:1345-50
The effect of preovulatory peritoneal fluid from cases of endometriosis on murine in vitro fertilization, embryo development, oviduct transport, and implantation (Dodds et al). 1992;166:219-24
Gonadotropin-releasing hormone agonists: strategies for managing the hypoestrogenic effects of therapy (Judd). 1992;166:752-6

Gonadotropin-releasing hormone analogs: update on new findings (Henzl). 1992;166:757-61
Hormone treatment of endometriosis: the estrogen threshold hypothesis (Barbieri). 1992;166:740-5
Hysteroscopic myometrial biopsy: its use in diagnosing adenomyosis and its clinical application (McCausland). 1992;166:1619-28
Infertility and endometriosis: comparison of pregnancy outcomes with laparotomy versus laparoscopic techniques (Gant). 1992;166:1072-81
Nafarelin in the management of endometriosis: quality of life assessment (Burry). 1992;166:735-9
Substance P in peritoneal fluid (Sanfilippo et al). 1992;166:155-9

Endometrium
Prevalence of out-of-phase endometrial biopsy specimens (Peters et al). 1992;166:1738-46
Steroids receptors in the endometrium during clomiphene citrate treatment (Shabib and Pittrof) (Letter); (Fritz) (Reply). 1992;166:1866-7
Ultrastructure of the microvasculature in the human endometrium throughout the normal menstrual cycle (Roberts et al). 1992;166:1393-406

Endothelins
Attenuation of the vasoconstrictor effects of thromboxane and endothelin by nitric oxide in the human fetal-placental circulation (Myatt et al). 1992;166:224-30
Endothelin-1 and endothelin-2 levels are increased in the amniotic fluid of women with preterm labor and microbial invasion of the amniotic cavity (Romero et al). 1992;166:95-9
Immunoreactive circulating endothelin-1 in normal and hypertensive pregnancies (Schiff et al). 1992;166:624-8
Plasma endothelin levels in preeclampsia: elevation and correlation with uric acid levels and renal impairment (Clark et al). 1992;166:962-8

Endothelium
Preeclampsia, von Willebrand factor antigen, and endothelial cells (Blann) (Letter); (Taylor et al) (Reply). 1992;166:769-70
Prostaglandin- or endothelium-mediated vasodilation is not involved in the blunted responses of blood vessels to vasoconstrictors in pregnant rats (St-Louis and Sicotte). 1992;166:684-92
Ultrastructure of the microvasculature in the human endometrium throughout the normal menstrual cycle (Roberts et al). 1992;166:1393-406

Endothelium-derived relaxing factor
Effect of endothelium-derived relaxing factor inhibition on the umbilical-placental circulation in fetal lambs in utero (Chang et al). 1992;166:727-34
Endothelium-derived relaxing factor and indomethacin-sensitive contracting factor alter arterial contractile responses to thromboxane during pregnancy (Weiner et al). 1992;166:1171-81

Enkephalins
Elevated plasma Met-enkephalin levels in the human newborn are a poor indicator of perinatal stress (Martinez et al). 1992;166:1429-35

Enzymes
Human ovarian 17-ketosteroid oxidoreductase: unique characteristics of the granulosa-luteal cell and stromal enzyme (Barbieri). 1992;166:1117-26

Eosinophils
Eosinophilic cystitis during pregnancy (Chamberlin). 1992;166:28-9

Epidermal growth factor-urogastrone
Catecholamines modulate epidermal growth factor–induced prostaglandin E_2 production in amnion-like (WISH) cells by means of a cyclic adenosine monophosphate–dependent pathway (Su et al). 1992;166:236-41
Partial hydatidiform moles have impaired differentiated function (human chorionic gonadotropin and human placental lactogen secretion) in response to epidermal growth factor and 8-bromo-cyclic adenosine monophosphate (Morrish et al). 1992;166:160-6
Transforming growth factor-α and epidermal growth factor messenger ribonucleic acid and protein levels in human placentas from early, mid, and late gestation (Bissonnette et al). 1992;166:192-9

Epithelium
Regulation of growth of normal ovarian epithelial cells and ovarian cancer cell lines by transforming growth factor-β (Berchuck et al). 1992;166:676-84

Epoprostenol
Norgestimate: a clinical overview of a new progestin (Bringer). 1992;166:1969-77
Urinary excretion of prostacyclin and thromboxane metabolites in threatened preterm labor: effect of indomethacin and nylidrin (Kurki et al). 1992;166:150-4

Erythroblastosis, fetal
Chorionic villus sampling for fetal Rh typing: clinical implications (Kickler et al). 1992;166:1407-11
Derivation of new mathematic formulas for determining whether a D-positive father is heterozygous or homozygous for the D antigen (Kanter). 1992;166:61-3
Hemolytic disease of the fetus (Spinnato) (Letter); (Weiner) (Reply). 1992;166:1589-90
Human fetal bilirubin levels and fetal hemolytic disease (Weiner). 1992;166:1449-54
Severe anti-C hemolytic disease of the newborn (Bowman et al). 1992;166:1239-43

Erythromycin
Erythromycin, motilin, and meconium (Danielian) (Letter); (Nugent) (Reply). 1992;166:767-8
Erythromycin therapy in preterm premature rupture of the membranes: a prospective, randomized trial of 220 patients (Mercer et al). 1992;166:794-802
Ureaplasma urealyticum resistance to erythromycin: confirmed by clinical trial (Kundsin et al) (Letter); (Eschenbach et al) (Reply). 1992;166:1864-5

Estradiol
Both 17β-estradiol and tamoxifen induce c-*fos* messenger ribonucleic acid expression in human endometrial carcinoma grown in nude mice (Sakakibara et al). 1992;166:206-12
Hormone treatment of endometriosis: the estrogen threshold hypothesis (Barbieri). 1992;166:740-5
In the rhesus monkey placental retention after fetectomy at 121 to 130 days' gestation outlasts the normal duration of pregnancy (Nathanielsz et al). 1992;166:1529-35
Low-dosage micronized 17β-estradiol prevents bone loss in postmenopausal women (Ettinger et al). 1992;166:479-88
Use of two types of estradiol-releasing skin patches for menopausal patients in a tropical climate (McCarthy et al). 1992;166:2005-10

Estriol
Maternal serum α-fetoprotein, β-human chorionic gonad-

Estriol—cont'd
otropin, and unconjugated estriol levels in midtrimester trisomy 18 pregnancies (Greenberg et al). 1992;166:1388-92
Ultrasonographic dating of pregnancy causes significant errors in Down syndrome risk assessment that may be minimized by use of biparietal diameter–based means (Reynolds et al). 1992;166:872-7
Estrogen receptors; *see* **Receptors, estrogen**
Estrogen replacement therapy
The benefits and risks of hormone replacement therapy: an epidemiologic overview (Harlap). 1992;166:1986-92
Comparison of transdermal and oral estrogen/progestin replacement therapy: effects on serum lipids and lipoproteins (Crook et al). 1992;166:950-5
The effect of sex steroids on the skeleton in premenopausal women (Lindsay). 1992;166:1993-6
Introduction to steroids in the menopause (Samsioe). 1992;166:1980-5
Postmenopausal steroid replacement with micronized dehydroepiandrosterone: preliminary oral bioavailability and dose proportionality studies (Buster et al). 1992;166:1163-70
Prolonged effects of a novel, low-dosage continuous progestin–cyclic estrogen replacement program in postmenopausal women (Plunkett and Wolfe). 1992;166:117-21
The role of progestins in hormone replacement therapy (Lobo). 1992;166:1997-2004
Steroids from menarche to menopause: introduction (Mishell). 1992;166:1949
Use of two types of estradiol-releasing skin patches for menopausal patients in a tropical climate (McCarthy et al). 1992;166:2005-10
Estrogens
Hormone treatment of endometriosis: the estrogen threshold hypothesis (Barbieri). 1992;166:740-5
Lp(a) lipoprotein: relationship to cardiovascular disease risk factors, exercise, and estrogen (Lobo et al). 1992;166:1182-90
A reevaluation of estrogen status in postmenopausal women who smoke (Cassidenti et al). 1992;166:1444-8
Ethics
Abortion or motherhood, suicide and madness (Ryan). 1992;166:1029-36
Animals and ethics: how society's attitudes have changed (Fritzsche) (Letter); (Maharry) (Reply). 1992;166:1312-3
Contraceptive prevalence, reproductive health, and international morality (Diczfalusy). 1992;166:1037-43
Sex selection and early pregnancy fetal sex determination: ethics and personal freedom of choice (Stephens) (Letter); (Evans and Fletcher) (Reply). 1992;166:1024-5
Ethinyl estradiol
The efficacy and tolerability of norgestimate/ethinyl estradiol (250 μg of norgestimate/35 μg of ethinyl estradiol): results of an open, multicenter study of 59,701 women (Runnebaum et al). 1992;166 1963-8
Ethnic factors
Comparison of adenocarcinoma and squamous cell carcinoma of the uterine cervix: a population-based epidemiologic study (Anton-Culver et al). 1992;166:1507-14
Exercise
Arterial pressure response to maximal isometric exercise in pregnant women (Lotgering et al). 1992;166:538-42
Lp(a) lipoprotein: relationship to cardiovascular disease risk factors, exercise, and estrogen (Lobo et al). 1992;166:1182-90
Exercise test
Maternal and fetal cardiovascular responses to strenuous bicycle exercise (van Doorn et al). 1992;166:854-9

F

Family planning
Rates and outcomes of planned pregnancy after use of Norplant capsules, Norplant II rods, or levonorgestrel-releasing or copper TCu 380Ag intrauterine contraceptive devices (Sivin et al). 1992;166:1208-13
Fasciitis
Necrotizing fasciitis of the vulva (Stephenson et al). 1992;166:1324-7
Fatty acids, polyunsaturated
Polyunsaturated fatty acids in preeclampsia (Sanjurjo et al) (Letter); (Wang et al) (Reply). 1992;166:1023-4
Fertilization
Periconceptional exposure to topical 5-fluorouracil (Otaño et al) (Letter); (Plouffe et al) (Reply). 1992;166:263-4
Fertilization in vitro
The effect of preovulatory peritoneal fluid from cases of endometriosis on murine in vitro fertilization, embryo development, oviduct transport, and implantation (Dodds et al). 1992;166:219-24
Selection bias in in vitro fertilization programs (Hershlag et al). 1992;166:1-3 (Clin. opinion)
Fetal biophysical characteristics; *see* **Biophysics**
Fetal blood
Acute posttraumatic fetal anemia treated with fetal intravascular transfusion (Del Valle et al). 1992;166:127-9
Attenuation of the vasoconstrictor effects of thromboxane and endothelin by nitric oxide in the human fetal-placental circulation (Myatt et al). 1992;166:224-30
Changes in human fetal cerebral hemoglobin concentration and oxygenation during labor measured by near-infrared spectroscopy (Peebles et al). 1992;166:1369-73
Chorionic villus sampling for fetal Rh typing: clinical implications (Kickler et al). 1992;166:1407-11
Does amniotic fluid analysis reflect acid-base balance in fetal blood? (Economides et al). 1992;166:970-3
Doppler ultrasonographic features of the developing placental circulation: correlation with anatomic findings (Jauniaux et al). 1992;166:585-7
Effect of endothelium-derived relaxing factor inhibition on the umbilical-placental circulation in fetal lambs in utero (Chang et al). 1992;166:727-34
Effects of chronic maternal anemia on systemic and uteroplacental oxygenation in near-term pregnant sheep (Delpapa et al). 1992;166:1007-12
Elevated plasma Met-enkephalin levels in the human newborn are a poor indicator of perinatal stress (Martinez et al). 1992;166:1429-35
Enhanced sensitization after cordocentesis (Weiner) (Letter); (MacGregor et al) (Reply). 1992;166:1309-10
Fetal biophysical and umbilical cord gases (Modanlou) (Letter); (Vintzileos et al) (Reply). 1992;166:1589
Fetal polycythemia and thrombocytopenia in pregnancies complicated by maternal diabetes mellitus (Salvesen et al). 1992;166:1287-92
Hemolytic disease of the fetus (Spinnato) (Letter); (Weiner) (Reply). 1992;166:1589-90
Human fetal bilirubin levels and fetal hemolytic disease (Weiner). 1992;166:1449-54

Intracerebral, aortic, and umbilical artery flow velocity waveforms in the late-first-trimester fetus (Wladimiroff et al). 1992;166:46-9
Long-term acid-base measurements in the fetal and maternal baboon (Daniel et al). 1992;166:707-12
Normal fetal Doppler inferior vena cava, transtricuspid, and umbilical artery flow velocity waveforms between 11 and 16 weeks' gestation (Wladimiroff et al). 1992;166:921-4
Percutaneous umbilical blood sampling: results from a multicenter collaborative registry (Hickok et al). 1992;166:1614-8
Role of prostaglandins in the metabolic responses of the fetus to hypoxia (Hooper et al). 1992;166:1568-75
Uterine and umbilical flow velocity waveforms in normotensive and hypertensive subjects during the angiotensin II sensitivity test (Erkkola and Pirhonen). 1992;166:910-6

Fetal death
Repeated fetal losses associated with antiphospholipid antibodies: a collaborative randomized trial comparing prednisone with low-dose heparin treatment (Cowchock et al). 1992;166:1318-23

Fetal development
Composite assessment of gestational age: a comparison of institutionally derived and published regression equations (Hill et al). 1992;166:551-5
Comprehensive fetal assessment with three ultrasonographic characteristics (James et al). 1992;166:1486-95
The effect of preovulatory peritoneal fluid from cases of endometriosis on murine in vitro fertilization, embryo development, oviduct transport, and implantation (Dodds et al). 1992;166:219-24
Effects of antenatal thyrotropin-releasing hormone, antenatal corticosteroids, and postnatal ventilation on surfactant mobilization in premature rabbits (Seidner et al). 1992;166:1551-9
Efficacy of the fetal-pelvic index in nulliparous women at high risk for fetal-pelvic disproportion (Morgan and Thurnau). 1992;166:810-4
Inhibition of preimplantation mouse embryo development by isoflurane (Warren et al). 1992;166:693-8

Fetal diseases
The effect of fetal sepsis on umbilical cord gases (Meyer et al). 1992;166:612-7
Fetal polycythemia and thrombocytopenia in pregnancies complicated by maternal diabetes mellitus (Salvesen et al). 1992;166:1287-92
Prenatal diagnosis of autosomal recessive polycystic kidney disease: variable outcome within one family (Barth et al). 1992;166:560-7
Prenatal diagnosis of fetal cytomegalovirus infection (Lamy et al). 1992;166:91-4
Prenatal ultrasonographic diagnosis of fetal scrotal inguinal hernia (Meizner et al). 1992;166:907-9
Prognosis in fetal diaphragmatic hernia (Sharland et al). 1992;166:9-13
Transient severe unilateral and subsequent bilateral primary fetal hydrothorax with spontaneous resolution at 34 weeks' gestation associated with normal neonatal outcome (Sherer et al). 1992;166:169-70
What is the prognosis for congenital cytomegalovirus infection? (Binder). 1992;166:1591 (Letter)

Fetal distress
Intrapartum amniotic fluid index and its relationship to fetal distress (Robson et al). 1992;166:78-82
The short umbilical cord (Collins). 1992;166:268-9 (Letter)

Fetal growth
The use of neural network for the ultrasonographic estimation of fetal weight in the macrosomic fetus (Farmer et al). 1992;166:1467-72

Fetal growth retardation
Inferior vena cava flow velocity waveforms in appropriate- and small-for-gestational-age fetuses (Rizzo et al). 1992;166:1271-80
Low-dose infusion of atrial natriuretic peptide in the conscious guinea pig increases blood flow to the placenta of growth-retarded fetuses (Jansson). 1992;166:213-8
Middle cerebral artery flow velocity waveforms in normal and small-for-gestational-age fetuses (Mari and Deter). 1992;166:1262-70
Numeric analysis of heart rate variation in intrauterine growth-retarded fetuses: a longitudinal study (Snijders et al). 1992;166:22-7
Risk factors for small-for-gestational-age birth in a preterm population (Lang et al). 1992;166:1374-8
Venous drainage of the human uterus: respiratory gas studies in normal and fetal growth-retarded pregnancies (Pardi et al). 1992;166:699-706

Fetal heart; *see also* **Heart rate, fetal**
The accuracy of auscultatory detection of fetal cardiac decelerations: a computer simulation (Schifrin et al). 1992;166:566-76
Fetal echocardiography: accuracy and limitations in a population at high and low risk for heart defects (Bromley et al). 1992;166:1473-81
Prognosis in fetal diaphragmatic hernia (Sharland et al). 1992;166:9-13

Fetal intravascular transfusion; *see* **Blood transfusion, intrauterine**

Fetal macrosomia
The use of neural network for the ultrasonographic estimation of fetal weight in the macrosomic fetus (Farmer et al). 1992;166:1467-72

Fetal membranes
Effects of platelet-activating factor on prostaglandin E_2 production by intact fetal membranes (Morris et al). 1992;166:1228-31
Influence of labor and oxytocin on in vitro leukotriene release by human fetal membranes and uterine decidua at term gestation (Pasetto et al). 1992;166:1500-6

Fetal membranes, premature rupture
Comment on fetal breathing movements after premature rupture of membranes (Kivikoski and Amon) (Letter); (Roberts) (Reply). 1992;166:770
Direct inhibition of proteases and cervical plasminogen activator by antibiotics (Milwidsky et al). 1992;166:606-12
Eradication of *Ureaplasma urealyticum* from the amniotic fluid with transplacental antibiotic treatment (Romero et al). 1992;166:618-20
Erythromycin therapy in preterm premature rupture of the membranes: a prospective, randomized trial of 220 patients (Mercer et al). 1992;166:794-802
Infection and labor. VII. Microbial invasion of the amniotic cavity in spontaneous rupture of membranes at term (Romero et al). 1992;166:129-33
Preterm premature rupture of membranes: results of expectant management in patients with cervical cultures

Fetal membranes, premature rupture—cont'd
positive for group B streptococcus or *Neisseria gonorrhoeae* (Maxwell and Watson). 1992;166:945-9
Prostaglandin E_2 for induction of labor in patients with premature rupture of membranes at term (Ray and Garite). 1992;166:836-43
Serial thoracic versus abdominal circumference ratios for the prediction of pulmonary hypoplasia in premature rupture of the membranes remote from term (D'Alton et al). 1992;166:658-63
Fetal monitoring
Actocardiotocographic monitoring of triplets during vaginal delivery (van Eyck and Arabin). 1992;166:1293-4
Change in electrocardiogram T-wave amplitude during umbilical cord compression is predictive of fetal condition in sheep (Watanabe et al). 1992;166:246-55
Comprehensive fetal assessment with three ultrasonographic characteristics (James et al). 1992;166:1486-95
A controlled trial of self–nonstress test versus assisted nonstress test in the evaluation of fetal well-being (Reece et al). 1992;166:489-92
Details of electronic fetal monitoring randomized control trials (Schifrin) (Letter); (Ellison) (Reply). 1992;166:1308-9
First report: telemetry-assisted ambulatory nonstress test (Collins). 1992;166:1020-1 (Letter)
Population differences of fetal biophysical and behavioral characteristics (Johnson et al). 1992;166:138-42
Fetal organ maturity
Comment on fetal breathing movements after premature rupture of membranes (Kivikoski and Amon) (Letter); (Roberts) (Reply). 1992;166:770
The effects of glycemia on breathing movements and plasma prostaglandin E concentrations in the sheep fetus (Fowden et al). 1992;166:713-9
Mimicking low amniotic pressure by chronic pharyngeal drainage does not impair lung development in fetal sheep (Fisk et al). 1992;166:991-6
Prediction of respiratory distress syndrome by a new colorimetric assay (Almog et al). 1992;166:1827-34
Fetal-pelvic disproportion
Efficacy of the fetal-pelvic index in nulliparous women at high risk for fetal-pelvic disproportion (Morgan and Thurnau). 1992;166:810-4
Fetal urine; *see* **Urine**
Fetectomy
In the rhesus monkey placental retention after fetectomy at 121 to 130 days' gestation outlasts the normal duration of pregnancy (Nathanielsz et al). 1992;166:1529-35
Fetofetal transfusion
Therapeutic amniocentesis in twin-twin transfusion syndrome appearing in the second trimester of pregnancy (Saunders et al). 1992;166:320-4
Fetoscopy
Does amniotic fluid analysis reflect acid-base balance in fetal blood? (Economides et al). 1992;166:970-3
Fetus, drug effects
The maternal and fetal effects of milrinone and dopamine in normotensive pregnant ewes (Santos et al). 1992;166:257-62
Fibronectins
The function of elevated plasma fibronectin in preeclampsia (Brubaker et al). 1992;166:526-31
First trimester of pregnancy; *see* **Pregnancy trimester, first**
Fistula
Omental graft made simple (Petty). 1992;166:1591 (Letter)
Flecainide
Treatment of fetal supraventricular tachycardia with flecainide acetate after digoxin failure (Mills) (Letter); (Kofinas) (Reply). 1992;166:1863
Flora; *see* **Bacteria**
Flow cytometry
Deoxyribonucleic acid analysis by flow cytometry of uterine leiomyosarcomas and smooth muscle tumors of uncertain malignant potential (Peters et al). 1992;166:1646-54
Flow velocity; *see* **Blood flow velocity**
Flowmeters
Applicability of the Poiseuille equation to umbilical artery velocimetry (Degani) (Letter); (Wright and Ridgway) (Reply). 1992;166:766-7
Comparison of dynamic image and pulsed Doppler ultrasonography for the diagnosis of the small-for-gestational-age fetus (Miller and Gabert). 1992;166:1820-6
Fluoresceins
Infarction of the uterus from subacute incomplete inversion (Romo et al). 1992;166:878-9
Fluorouracil
Periconceptional exposure to topical 5-fluorouracil (Otaño et al) (Letter); (Plouffe et al) (Reply). 1992;166:263-4
Superficial laser vulvectomy. V. Surgical debulking is enhanced by adjuvant systemic interferon (Reid et al). 1992;166:815-20
Folic acid
Oral folic acid supplementation for cervical dysplasia: a clinical intervention trial (Butterworth et al). 1992;166:803-9
Frozen sections
Accuracy of frozen-section diagnosis at surgery in clinical state I and II endometrial carcinoma (Shim et al). 1992;166:1335-8
Frozen semen; *see* **Semen preservation**

G

Genes
Rapid identification of deoxyribonucleic acid sequence differences in cytochrome P-450 21-hydroxylase (CYP21) genes with denaturing gradient gel blots (Reindollar et al). 1992;166:184-91
Genetic screening
Triplet pregnancy involving complete hydatidiform mole and two fetuses: genetic analysis by deoxyribonucleic acid fingerprint (Azuma et al). 1992;166:664-7
Genetics
Familial occurrence of thrombotic thrombocytopenic purpura in two sisters during pregnancy (Wiznitzer et al). 1992;166:20-1
Genital diseases, female
The mechanisms of preterm labor: common genital tract pathogens do not metabolize arachidonic acid to prostaglandins or to other eicosanoids (Bennett and Elder). 1992;166:1541-5
Genitalia, female
Acute genital injury in the prepubertal girl (Pokorny et al). 1992;166:1461-6
Colposcopy to establish physical findings in rape victims (Slaughter and Brown). 1992;166:83-6
Gestational age
Composite assessment of gestational age: a comparison of

institutionally derived and published regression equations (Hill et al). 1992;166:551-5
Crown-rump length dating of pregnancy at less than 9 weeks' gestation (Cadkin). 1992;166:269 (Letter)
The frequency of breech presentation by gestational age at birth: a large population-based study (Hickok et al). 1992;166:851-2
Neonatal morbidity according to gestational age and birth weight from five tertiary care centers in the United States, 1983 through 1986 (Robertson et al). 1992;166:1629-45
The tip of the iceberg and the best fit in ultrasonographic dating of pregnancy (Rossavik) (Letter); (Goldstein) (Reply). 1992;166:1867-8
Ultrasonographic dating of pregnancy causes significant errors in Down syndrome risk assessment that may be minimized by use of biparietal diameter–based means (Reynolds et al). 1992;166:872-7
Validity of postnatal assessments of gestational age: a comparison of the method of Ballard et al. and early ultrasonography (Alexander et al). 1992;166:891-5

Gestational diabetes; *see* **Pregnancy in diabetes**

Gloves, surgical
Latex anaphylaxis in an obstetrics and gynecology physician (Chen et al). 1992;166:968-9

Glucose
Amniotic fluid glucose and intraamniotic infection: sensitivity, specificity, and predictive values (Gonen) (Letter); (Kirshon) (Reply). 1992;166:1863-4
Maternal glucose intolerance and the subcutaneous terbutaline pump (Lindenbaum et al). 1992;166:925-8
Treatment of unruptured tubal pregnancy by laparoscopic instillation of hyperosmolar glucose solution (Lang et al). 1992;166:1378-81

Glucose tolerance test
The effect of continuous subdermal levonorgestrel (Norplant) on carbohydrate metabolism (Konje et al). 1992;166:15-9

Glyceryl trinitrate
Intravenous nitroglycerin for uterine relaxation of an inverted uterus (Altabef et al). 1992;166:1237-8

Glycoproteins
Immunohistochemical detection of the multi-drug-resistance marker P-glycoprotein in uterine cervical carcinomas and normal cervical tissue (Schneider et al). 1992;166:825-9

Gonadorelin
Bioavailability of nafarelin in healthy volunteers (Chaplin). 1992;166:762-5
Gonadotropin-releasing hormone agonists: strategies for managing the hypoestrogenic effects of therapy (Judd). 1992;166:752-6
Gonadotropin-releasing hormone analogs: update on new findings (Henzl). 1992;166:757-61
Hormone treatment of endometriosis: the estrogen threshold hypothesis (Barbieri). 1992;166:740-5
Lipid and apolipoprotein abnormalities in hirsute women. I. The association with insulin resistance (Wild et al). 1992;166:1191-7
A model-based prediction for transvaginal ultrasonographic identification of early intrauterine pregnancy (Shapiro et al). 1992;166:1495-500
Nafarelin in the management of endometriosis: quality of life assessment (Burry). 1992;166:735-9
Treatment of uterine fibroids: current findings with gonadotropin-releasing hormone agonists (Adamson). 1992;166:746-51

Gonadotropin-releasing hormone; *see* **Gonadorelin**

Gonadotropins
Effect of controlled ovarian hyperstimulation on pregnancy rates after intrauterine insemination (DiMarzo et al). 1992;166:1607-13
Gonadotropin and ovarian hormone dynamics in luteal phase defects (Alexander et al). 1992;166:652-7
Triplet pregnancy involving complete hydatidiform mole and two fetuses: genetic analysis by deoxyribonucleic acid fingerprint (Azuma et al). 1992;166:664-7
Ultrasonographic dating of pregnancy causes significant errors in Down syndrome risk assessment that may be minimized by use of biparietal diameter–based means (Reynolds et al). 1992;166:872-7

Gonadotropins, chorionic
Maternal serum α-fetoprotein, β-human chorionic gonadotropin, and unconjugated estriol levels in midtrimester trisomy 18 pregnancies (Greenberg et al). 1992;166:1388-92
Partial hydatidiform moles have impaired differentiated function (human chorionic gonadotropin and human placental lactogen secretion) in response to epidermal growth factor and 8-bromo-cyclic adenosine monophosphate (Morrish et al). 1992;166:160-6

Government
Folly, woodenheadedness, and the alluvial mind: presidential address (Bolton). 1992;166:1595-6

Graft survival
Omental graft made simple (Petty). 1992;166:1591 (Letter)

Gram stain; *see* **Stains and staining**

Granulosa cells
Human ovarian 17-ketosteroid oxidoreductase: unique characteristics of the granulosa-luteal cell and stromal enzyme (Barbieri). 1992;166:1117-26

Graphic monitoring; *see* **Fetal monitoring**

Great Britain
First successful cesarean section in the British empire (Miller). 1992;166:269 (Letter)

Grief
Depressive symptoms in women in the 6 months after miscarriage (Neugebauer et al). 1992;166:104-9

Group B streptococcus; *see* ***Streptococcus agalactiae***

Growth retarded fetus; *see* **Fetal growth retardation**

H

Heart defects, congenital
Fetal echocardiography: accuracy and limitations in a population at high and low risk for heart defects (Bromley et al). 1992;166:1473-81

Heart diseases
Lp(a) lipoprotein: relationship to cardiovascular disease risk factors, exercise, and estrogen (Lobo et al). 1992;166:1182-90

Heart rate, fetal
The accuracy of auscultatory detection of fetal cardiac decelerations: a computer simulation (Schifrin et al). 1992;166:566-76
Change in electrocardiogram T-wave amplitude during umbilical cord compression is predictive of fetal condition in sheep (Watanabe et al). 1992;166:246-55
Changes in human fetal cerebral hemoglobin concentration and oxygenation during labor measured by near-infrared spectroscopy (Peebles et al). 1992;166:1369-73

Heart rate, fetal—cont'd
A controlled trial of self–nonstress test versus assisted nonstress test in the evaluation of fetal well-being (Reece et al). 1992;166:489-92
Details of electronic fetal monitoring randomized control trials (Schifrin) (Letter); (Ellison) (Reply). 1992;166:1308-9
First report: telemetry-assisted ambulatory nonstress test (Collins). 1992;166:1020-1 (Letter)
Maternal and fetal cardiovascular responses to strenuous bicycle exercise (van Doorn et al). 1992;166:854-9
Numeric analysis of heart rate variation in intrauterine growth-retarded fetuses: a longitudinal study (Snijders et al). 1992;166:22-7
The physiologic mechanisms of variable decelerations (Ball and Parer). 1992;166:1683-9
Population differences of fetal biophysical and behavioral characteristics (Johnson et al). 1992;166:138-42
Treatment of fetal supraventricular tachycardia with flecainide acetate after digoxin failure (Mills) (Letter); (Kofinas) (Reply). 1992;166:1863

HELLP syndrome
Intravenous immunoglobulins in postpartum, persistently severe HELLP syndrome: A safe alternative to plasma exchange? (Pourrat et al) (Letter); (Files and Martin) (Reply). 1992;166:766

Hemangioma
Infarction of placental chorioangioma and associated regression of hydrops fetalis (Hsieh and Soong) (Letter); (Chazotte et al) (Reply). 1992;166:1306

Hematoma
Postpartum paravaginal hematoma and lower-extremity infection (Chatwani et al). 1992;166:598-600

Hemoglobins
Changes in human fetal cerebral hemoglobin concentration and oxygenation during labor measured by near-infrared spectroscopy (Peebles et al). 1992;166:1369-73

Hemolytic anemia; *see* **Anemia, hemolytic**

Hemolytic disease of newborn; *see* **Erythroblastosis, fetal**

Hemorrhage
Angiographic embolization in the management of hemorrhagic complications of pregnancy (Gilbert et al). 1992;166:493-7
The effect of cesarean section on intraventricular hemorrhage in the preterm infant (Anderson et al). 1992;166:1091-101
Lack of reactivity of uterine arteries from patients with obstetric hemorrhage (Nelson and Suresh). 1992;166:1436-43
Neonatal morbidity according to gestational age and birth weight from five tertiary care centers in the United States, 1983 through 1986 (Robertson et al). 1992;166:1629-45

Hemostasis
Effects of mefenamic acid on menstrual hemostasis in essential menorrhagia (van Eijkeren et al). 1992;166:1419-28

Heparin
Repeated fetal losses associated with antiphospholipid antibodies: a collaborative randomized trial comparing prednisone with low-dose heparin treatment (Cowchock et al). 1992;166:1318-23

Hernia, diaphragmatic
Prognosis in fetal diaphragmatic hernia (Sharland et al). 1992;166:9-13

Hernia, inguinal
Prenatal ultrasonographic diagnosis of fetal scrotal inguinal hernia (Meizner et al). 1992;166:907-9

Heterozygote
Derivation of new mathematic formulas for determining whether a D-positive father is heterozygous or homozygous for the D antigen (Kanter). 1992;166:61-3

Hippocampus
Anticonvulsant effects of magnesium sulfate on hippocampal seizures: therapeutic implications in preeclampsia-eclampsia (Cotton et al). 1992;166:1127-36

Hirsutism
Lipid and apolipoprotein abnormalities in hirsute women. I. The association with insulin resistance (Wild et al). 1992;166:1191-7

Histocompatibility antigens
Impact of histocompatibility antigens on pregnancy outcome (Eroglu et al). 1992;166:1364-9

Historical article
First successful cesarean section in the British empire (Miller). 1992;166:269 (Letter)

HIV
Human vaginal leukocytes and the effects of vaginal fluid on lymphocyte and macrophage defense functions (Hill and Anderson). 1992;166:720-6
Papanicolaou smear abnormalities in ambulatory care sites for women infected with the human immunodeficiency virus (Marte et al). 1992;166:1232-7

Homeostasis
Renal autoregulation in midterm and late-pregnant rats (Reckelhoff et al). 1992;166:1546-50

Homozygote
Derivation of new mathematic formulas for determining whether a D-positive father is heterozygous or homozygous for the D antigen (Kanter). 1992;166:61-3

Hormone replacement therapy; *see* **Estrogen replacement therapy**

Hormones
Hormone treatment of endometriosis: the estrogen threshold hypothesis (Barbieri). 1992;166:740-5

Hospitalization
Hospitalization for pregnancy complications, United States, 1986 and 1987 (Franks et al). 1992;166:1339-44
Pelvic inflammatory disease: trends in hospitalizations and office visits, 1979 through 1988 (Rolfs et al). 1992;166:983-90
Tubal sterilization and risk of subsequent hospital admission for menstrual disorders (Shy et al). 1992;166:1698-706

Human chorionic gonadotropin; *see* **Gonadotropins, chorionic**

Human immunodeficiency virus; *see* **HIV**

Human papillomaviruses; *see* **Papillomaviruses**

Human rights
The issue of animal rights and human rights (Heller). 1992;166:1588-9 (Letter)

Humerus
Fetal humeral length to detect Down syndrome (Rotmensch et al). 1992;166:1330-4

Hyaluronic acid
Circulating hyaluronic acid in nonpregnant, pregnant, and postpartum guinea pigs: elevated levels observed at parturition (Rajabi et al). 1992;166:242-6

Hydatidiform mole
Partial hydatidiform moles have impaired differentiated function (human chorionic gonadotropin and human pla-

cental lactogen secretion) in response to epidermal growth factor and 8-bromo-cyclic adenosine monophosphate (Morrish et al). 1992;166:160-6
Triplet pregnancy involving complete hydatidiform mole and two fetuses: genetic analysis by deoxyribonucleic acid fingerprint (Azuma et al). 1992;166:664-7

Hydrocortisone
Oxytocin given in a pulsatile manner to the ewe at 120 to 140 days' gestational age increases fetal sheep plasma cortisol (Sadowsky et al). 1992;166:200-5

Hydrops fetalis
Hydrops fetalis associated with congenital myotonic dystrophy (Afifi et al). 1992;166:929-30
Infarction of placental chorioangioma and associated regression of hydrops fetalis (Hsieh and Soong) (Letter); (Chazotte et al) (Reply). 1992;166:1306

Hydrothorax
Transient severe unilateral and subsequent bilateral primary fetal hydrothorax with spontaneous resolution at 34 weeks' gestation associated with normal neonatal outcome (Sherer et al). 1992;166:169-70

Hydroxybutyrates
Effects of β-hydroxybutyrate infusion on hind limb metabolism in fetal sheep (Harding et al). 1992;166:671-6

Hydroxylases
Rapid identification of deoxyribonucleic acid sequence differences in cytochrome P-450 21-hydroxylase (CYP21) genes with denaturing gradient gel blots (Reindollar et al). 1992;166:184-91

Hydroxyurea
Hydroxyurea and pregnancy (Tertian et al). 1992;166:1868 (Letter)

Hyperosmolar glucose solution; *see* **Glucose**

Hypersensitivity
Latex anaphylaxis in an obstetrics and gynecology physician (Chen et al). 1992;166:968-9

Hypertension
Eclampsia. VII. Pregnancy outcome after eclampsia and long-term prognosis (Sibai et al). 1992;166:1757-63
Immunoreactive circulating endothelin-1 in normal and hypertensive pregnancies (Schiff et al). 1992;166:624-8
Interrelationship and clinical significance of increased resistance in the uterine arteries in patients with hypertension or preeclampsia or both (Kofinas et al). 1992;166:601-6
Platelet activation and vascular damage in gestational hypertension (Ballegeer et al). 1992;166:629-33
Polyunsaturated fatty acids in preeclampsia (Sanjurjo et al) (Letter); (Wang et al) (Reply). 1992;166:1023-4
Progression of diabetic retinopathy in pregnancy: association with hypertension in pregnancy (Rosenn et al). 1992;166:1214-8
Uterine and umbilical flow velocity waveforms in normotensive and hypertensive subjects during the angiotensin II sensitivity test (Erkkola and Pirhonen). 1992;166:910-6

Hypoglycemia
The effects of glycemia on breathing movements and plasma prostaglandin E concentrations in the sheep fetus (Fowden et al). 1992;166:713-9
Impairment of counterregulatory hormone responses to hypoglycemia in pregnant women with insulin-dependent diabetes mellitus (Diamond et al). 1992;166:70-7

Hypothermia
Hypothermia revisited (Kaplan and Eidelman) (Letter); (Hazan et al) (Reply). 1992;166:768-9

Hysterectomy
Anatomic aspects of vaginal eversion after hysterectomy (DeLancey). 1992;166:1717-28
Influence of alcohol intake on postoperative morbidity after hysterectomy (Felding et al). 1992;166:667-70
Patterns of failure of bulky-barrel carcinomas of the cervix (Coleman et al). 1992;166:916-20
Radical hysterectomy for treatment of cervical cancer: a prospective study of two methods of closed-suction drainage (Barton et al). 1992;166:533-7
Radical hysterectomy in the elderly patient: analysis of morbidity (Fuchtner et al). 1992;166:593-7

Hysterectomy, vaginal
Laparoscopic radical hysterectomy with paraaortic and pelvic node dissection (Nezhat et al). 1992;166:864-5
Prophylactic sacrospinous fixation discouraged (Scotti) (Letter); (Cruikshank) (Reply). 1992;166:1022-3

Hysteroscopy
Documentation of high-molecular-weight dextran (Hyskon) solution entering the serum during hysteroscopy (Mangar). 1992;166:771 (Letter)
Hysteroscopic myometrial biopsy: its use in diagnosing adenomyosis and its clinical application (McCausland). 1992;166:1619-28

I

Ifosfamide
Phase II trial of ifosfamide and mesna in leiomyosarcoma of the uterus: a gynecologic oncology group study (Sutton et al). 1992;166:556-9

Immunity, cellular
Cellular immunity of patients with recurrent or refractory vulvovaginal moniliasis (Fong et al). 1992;166:887-90
Evidence of embryo- and trophoblast-toxic cellular immune response(s) in women with recurrent spontaneous abortion (Hill et al). 1992;166:1044-52

Immunoassay
Use of urinary luteinizing hormone immunoassays in the assessment of luteal function in infertile women (Corsan et al). 1992;166:41-6

Immunoglobulins
Intravenous immunoglobulins in postpartum, persistently severe HELLP syndrome: A safe alternative to plasma exchange? (Pourrat et al) (Letter); (Files and Martin) (Reply). 1992;166:766

Immunohistochemistry
Immunohistochemical detection of the multi-drug-resistance marker P-glycoprotein in uterine cervical carcinomas and normal cervical tissue (Schneider et al). 1992;166:825-9
The utility of immunocytochemistry in invasive adenocarcinoma of the cervix (Tamimi et al). 1992;166:1655-62

Implantation; *see* **Ovum implantation**

In utero platelet transfusion; *see* **Blood transfusion, intrauterine**

In vitro fertilization; *see* **Fertilization in vitro**

Indomethacin
Endothelium-derived relaxing factor and indomethacin-sensitive contracting factor alter arterial contractile responses to thromboxane during pregnancy (Weiner et al). 1992;166:1171-81

Indomethacin—cont'd
Role of prostaglandins in the metabolic responses of the fetus to hypoxia (Hooper et al). 1992;166:1568-75
Urinary excretion of prostacyclin and thromboxane metabolites in threatened preterm labor: effect of indomethacin and nylidrin (Kurki et al). 1992;166:150-4
Induction of ovulation; *see* **Ovulation induction**
Infant, low birth weight
Breech extraction of low-birth-weight second twins: Can cesarean section be justified? (Davison et al). 1992; 166:497-502
Drug use or inadequate prenatal care? Adverse pregnancy outcome in an urban setting (Broekhuizen et al). 1992;166:1747-56
Risk factors for small-for-gestational-age birth in a preterm population (Lang et al). 1992;166:1374-8
Infant, newborn
Alloimmune thrombocytopenia may be associated with systemic disease (Kay et al). 1992;166:110-1
Does oxytocin augmentation increase perinatal risk in primigravid labor? (Cahill et al). 1992;166:847-50
The effect of fetal sepsis on umbilical cord gases (Meyer et al). 1992;166:612-7
Elevated plasma Met-enkephalin levels in the human newborn are a poor indicator of perinatal stress (Martinez et al). 1992;166:1429-35
Neonatal morbidity according to gestational age and birth weight from five tertiary care centers in the United States, 1983 through 1986 (Robertson et al). 1992;166:1529-45
Infant, postmature
Validity of postnatal assessments of gestational age: a comparison of the method of Ballard et al. and early ultrasonography (Alexander et al). 1992;166:891-5
Infant, premature
The effect of cesarean section on intraventricular hemorrhage in the preterm infant (Anderson et al). 1992; 166:1091-101
Effects of antenatal thyrotropin-releasing hormone, antenatal corticosteroids, and postnatal ventilation on surfactant mobilization in premature rabbits (Seidner et al). 1992;166:1551-9
Hypothermia revisited (Kaplan and Eidelman) (Letter); (Hazan et al) (Reply). 1992;166:768-9
A review of premature birth and subclinical infection (Gibbs et al). 1992;166:1515-28 (Curr. dev.)
Risk factors for small-for-gestational-age birth in a preterm population (Lang et al). 1992;166:1374-8
Spontaneous abortion and subsequent adverse birth outcomes (Thom et al). 1992;166:111-6
Validity of postnatal assessments of gestational age: a comparison of the method of Ballard et al. and early ultrasonography (Alexander et al). 1992;166:891-5
Infant, small for gestational age
Comparison of dynamic image and pulsed Doppler ultrasonography for the diagnosis of the small-for-gestational-age fetus (Miller and Gabert). 1992;166:1820-6
Inferior vena cava flow velocity waveforms in appropriate- and small-for-gestational-age fetuses (Rizzo et al). 1992;166:1271-80
Middle cerebral artery flow velocity waveforms in normal and small-for-gestational-age fetuses (Mari and Deter). 1992;166:1262-70
Risk factors for small-for-gestational-age birth in a preterm population (Lang et al). 1992;166:1374-8
Validity of postnatal assessments of gestational age: a comparison of the method of Ballard et al. and early ultrasonography (Alexander et al). 1992;166:891-5
Infant mortality
Main clinical types and subtypes of eclampsia (López-Llera). 1992;166:4-9
Suffer the little children: presidential address (Youngblood). 1992;166:1712-6
Infarction
Infarction of placental chorioangioma and associated regression of hydrops fetalis (Hsieh and Soong) (Letter); (Chazotte et al) (Reply). 1992;166:1306
Infarction of the uterus from subacute incomplete inversion (Romo et al). 1992;166:878-9
Infection; *see also* **Pregnancy complications, infectious**
Amniotic fluid glucose and intraamniotic infection: sensitivity, specificity, and predictive values (Gonen) (Letter); (Kirshon) (Reply). 1992;166:1863-4
The mechanisms of preterm labor: common genital tract pathogens do not metabolize arachidonic acid to prostaglandins or to other eicosanoids (Bennett and Elder). 1992;166:1541-5
Postpartum paravaginal hematoma and lower-extremity infection (Chatwani et al). 1992;166:598-600
A review of premature birth and subclinical infection (Gibbs et al). 1992;166:1515-28 (Curr. dev.)
Inferior vena cava; *see* **Vena cava, inferior**
Infertility, female
Buserelin acetate versus expectant management in the treatment of infertility associated with minimal or mild endometriosis: a randomized clinical trial (Fedele et al). 1992;166:1345-50
Criteria for the diagnosis of infertility (Kessopoulou et al) (Letter); (Aitken) (Reply). 1992;166:264-5
Infertility and endometriosis: comparison of pregnancy outcomes with laparotomy versus laparoscopic techniques (Gant). 1992;166:1072-81
Infertility and pregnancy outcome in an unselected group of women with insulin-dependent diabetes mellitus (Kjaer et al). 1992;166:1412-8
Long-term sequelae of acute pelvic inflammatory disease: a retrospective cohort study (Safrin et al). 1992;166: 1300-5
Ovarian carcinoma of low malignant potential, infertility, and induction of ovulation: Is there a link? (Goldberg and Runowicz). 1992;166:853-4
Prevalence of out-of-phase endometrial biopsy specimens (Peters et al). 1992;166:1738-46
Use of urinary luteinizing hormone immunoassays in the assessment of luteal function in infertile women (Corsan et al). 1992;166:41-6
Inflammation
The relationship between acute inflammatory lesions of the preterm placenta and amniotic fluid microbiology (Romero et al). 1992;166:1382-8
Infusion pumps
Maternal glucose intolerance and the subcutaneous terbutaline pump (Lindenbaum et al). 1992;166:925-8
Infusions, intravenous
Effects of β-hydroxybutyrate infusion on hind limb metabolism in fetal sheep (Harding et al). 1992;166: 671-6
Low-dose infusion of atrial natriuretic peptide in the conscious guinea pig increases blood flow to the placenta of growth-retarded fetuses (Jansson). 1992;166:213-8
Oxytocin given in a pulsatile manner to the ewe at 120 to

140 days' gestational age increases fetal sheep plasma cortisol (Sadowsky et al). 1992;166:200-5
Transient symptomatic subendocardial ischemia during intravenous magnesium sulfate tocolytic therapy (Sherer et al). 1992;166:33-5

Inguinal hernia; *see* **Hernia, inguinal**

Insemination, artificial
Effect of controlled ovarian hyperstimulation on pregnancy rates after intrauterine insemination (DiMarzo et al). 1992;166:1607-13
Therapeutic donor insemination: a prospective randomized trial of fresh versus frozen sperm (Subak et al). 1992;166:1597-606

Insulin
Impairment of counterregulatory hormone responses to hypoglycemia in pregnant women with insulin-dependent diabetes mellitus (Diamond et al). 1992;166:70-7

Insulin-dependent diabetes mellitus; *see* **Diabetes mellitus, insulin-dependent**

Insulin-like growth factor I
Insulin-like growth factor I and II binding in human myometrium and leiomyomas (Chandrasekhar et al). 1992;166:64-9

Insulin-like growth factor II
Insulin-like growth factor I and II binding in human myometrium and leiomyomas (Chandrasekhar et al). 1992;166:64-9

Insulin resistance
Lipid and apolipoprotein abnormalities in hirsute women. I. The association with insulin resistance (Wild et al). 1992;166:1191-7

Interferons
Superficial laser vulvectomy. V. Surgical debulking is enhanced by adjuvant systemic interferon (Reid et al). 1992;166:815-20

Interleukin-6
Stimulation of ovarian tumor cell proliferation with monocyte products, including interleukin-α, interleukin-6, and tumor necrosis factor-α (Wu et al). 1992;166:997-1007

Interleukins
Stimulation of ovarian tumor cell proliferation with monocyte products, including interleukin-α, interleukin-6, and tumor necrosis factor-α (Wu et al). 1992;166:997-1007

Internship and residency
Emergency room use of transvaginal ultrasonography by obstetrics and gynecology residents (Timor-Tritsch et al). 1992;166:866-72
Resident attrition in obstetrics and gynecology (Seltzer et al). 1992;166:1315-7
Training obstetric and family practice residents to give smoking cessation advice during prenatal care (Secker-Walker et al). 1992;166:1356-63

Intracerebral artery; *see* **Cerebral arteries**

Intrauterine devices
Rates and outcomes of planned pregnancy after use of Norplant capsules, Norplant II rods, or levonorgestrel-releasing or copper TCu 380Ag intrauterine contraceptive devices (Sivin et al). 1992;166:1208-13

Intrauterine devices, copper
Rates and outcomes of planned pregnancy after use of Norplant capsules, Norplant II rods, or levonorgestrel-releasing or copper TCu 380Ag intrauterine contraceptive devices (Sivin et al). 1992;166:1208-13

Intrauterine growth retardation; *see* **Fetal growth retardation**

Intraventricular hemorrhage; *see* **Hemorrhage**

Inversion of uterus; *see* **Uterine diseases**

Inverted uterus; *see* **Uterus**

Ischemia
Transient symptomatic subendocardial ischemia during intravenous magnesium sulfate tocolytic therapy (Sherer et al). 1992;166:33-5

Isoflurane
Inhibition of preimplantation mouse embryo development by isoflurane (Warren et al). 1992;166:693-8

Items
Items. 1992;166:272, 772, 1028, 1314, 1594, 1892

K

Ketones
Effects of β-hydroxybutyrate infusion on hind limb metabolism in fetal sheep (Harding et al). 1992;166:671-6

Ketosteroids
Human ovarian 17-ketosteroid oxidoreductase: unique characteristics of the granulosa-luteal cell and stromal enzyme (Barbieri). 1992;166:1117-26

Kidney
Fetal urine biochemistry in the assessment of obstructive uropathy (Nicolaides et al). 1992;166:932-7
Renal autoregulation in midterm and late-pregnant rats (Reckelhoff et al). 1992;166:1546-50

Kidney, polycystic
Prenatal diagnosis of autosomal recessive polycystic kidney disease: variable outcome within one family (Barth et al). 1992;166:560-7

Kidney diseases
Plasma endothelin levels in preeclampsia: elevation and correlation with uric acid levels and renal impairment (Clark et al). 1992;166:962-8

Killer cells, natural
Natural killer cell activity from pregnant subjects is modulated by RU 486 (Hansen et al). 1992;166:87-90

L

Labor
Acute childbirth morbidity: its measurement using hospital charges (Hage et al). 1992;166:1853-62
Changes in human fetal cerebral hemoglobin concentration and oxygenation during labor measured by near-infrared spectroscopy (Peebles et al). 1992;166:1369-73
Circulating hyaluronic acid in nonpregnant, pregnant, and postpartum guinea pigs: elevated levels observed at parturition (Rajabi et al). 1992;166:242-6
Does oxytocin augmentation increase perinatal risk in primigravid labor? (Cahill et al). 1992;166:847-50
The effect of cesarean section on intraventricular hemorrhage in the preterm infant (Anderson et al). 1992;166:1091-101
Effects of platelet-activating factor on prostaglandin E_2 production by intact fetal membranes (Morris et al). 1992;166:1228-31
Efficacy of the fetal-pelvic index in nulliparous women at high risk for fetal-pelvic disproportion (Morgan and Thurnau). 1992;166:810-4
Elective induction versus spontaneous labor: a retrospective study of complications and outcome (Macer et al). 1992;166:1690-7
The Green Bay cesarean section study. II. The physician

Labor—cont'd
factor as a determinant of cesarean birth rates for failed labor (DeMott and Sandmire). 1992;166:1799-810
In the rhesus monkey placental retention after fetectomy at 121 to 130 days' gestation outlasts the normal duration of pregnancy (Nathanielsz et al). 1992;166:1529-35
Infection and labor. VII. Microbial invasion of the amniotic cavity in spontaneous rupture of membranes at term (Romero et al). 1992;166:129-33
Influence of labor and oxytocin on in vitro leukotriene release by human fetal membranes and uterine decidua at term gestation (Pasetto et al). 1992;166:1500-6
Intrapartum amniotic fluid index and its relationship to fetal distress (Robson et al). 1992;166:78-82
Origin of cervical collagenase during parturition (Osmers et al). 1992;166:1455-60
Tumor necrosis factor in preterm and term labor (Romero et al). 1992;166:1576-87

Labor, induced
Elective induction versus spontaneous labor: a retrospective study of complications and outcome (Macer et al). 1992;166:1690-7
Factors affecting the dose response to oxytocin for labor stimulation (Satin et al). 1992;166:1260-1
Prostaglandin E_2 for induction of labor in patients with premature rupture of membranes at term (Ray and Garite). 1992;166:836-43
A randomized trial of prostaglandin E_2 in a controlled-release vaginal pessary for cervical ripening at term (Witter et al). 1992;166:830-4

Labor, premature
Direct inhibition of proteases and cervical plasminogen activator by antibiotics (Milwidsky et al). 1992;166:606-12
Elevated maternal plasma corticotropin-releasing hormone levels in pregnancies complicated by preterm labor (Warren et al). 1992;166:1198-207
Endothelin-1 and endothelin-2 levels are increased in the amniotic fluid of women with preterm labor and microbial invasion of the amniotic cavity (Romero et al). 1992;166:95-9
Maternal glucose intolerance and the subcutaneous terbutaline pump (Lindenbaum et al). 1992;166:925-8
The mechanisms of preterm labor: common genital tract pathogens do not metabolize arachidonic acid to prostaglandins or to other eicosanoids (Bennett and Elder). 1992;166:1541-5
Oral magnesium and the prevention of preterm labor in a high-risk group of patients (Martin et al). 1992;166:144-7
A randomized, placebo-controlled trial of betamethasone for the prevention of respiratory distress syndrome at 24 to 28 weeks' gestation (Garite et al). 1992;166:646-51
The relationship between acute inflammatory lesions of the preterm placenta and amniotic fluid microbiology (Romero et al). 1992;166:1382-8
Transient symptomatic subendocardial ischemia during intravenous magnesium sulfate tocolytic therapy (Sherer et al). 1992;166:33-5
Tumor necrosis factor in preterm and term labor (Romero et al). 1992;166:1576-87
Urinary excretion of prostacyclin and thromboxane metabolites in threatened preterm labor: effect of indomethacin and nylidrin (Kurki et al). 1992;166:150-4

Labor stage, first
A randomized trial of prostaglandin E_2 in a controlled-release vaginal pessary for cervical ripening at term (Witter et al). 1992;166:830-4

Laboratories
Interlaboratory variation in antiphospholipid antibody testing (Peaceman et al). 1992;166:1780-7

Lactates
Effects of β-hydroxybutyrate infusion on hind limb metabolism in fetal sheep (Harding et al). 1992;166:671-6

Laparoscopy; *see* **Peritoneoscopy**

Laparotomy
Infertility and endometriosis: comparison of pregnancy outcomes with laparotomy versus laparoscopic techniques (Gant). 1992;166:1072-81
Serum levels of macrophage colony-stimulating factor in patients with ovarian cancer undergoing second-look laparotomy (Elg et al). 1992;166:134-7

Laryngeal neoplasms
Fatal maternal laryngeal papillomatosis in pregnancy: a case report (Helmrich et al). 1992;166:524-5

Laser surgery
Comparison of thermal injury zones in loop electrical and laser cervical excisional conization (Baggish et al). 1992;166:545-8
Frontiers of operative laparoscopy: a review and critique of the evidence (Grimes). 1992;166:1062-71
Infertility and endometriosis: comparison of pregnancy outcomes with laparotomy versus laparoscopic techniques (Gant). 1992;166:1072-81
The need for technology assessment in the reproductive sciences (McDonough). 1992;166:1082-90
Superficial laser vulvectomy. V. Surgical debulking is enhanced by adjuvant systemic interferon (Reid et al). 1992;166:815-20

Latex
Latex anaphylaxis in an obstetrics and gynecology physician (Chen et al). 1992;166:968-9

Leadership
Leadership qualities of obstetrics and gynecology department chairmen of United States medical schools (Bates and Blackhurst). 1992;166:1102-16

Leg
Postpartum paravaginal hematoma and lower-extremity infection (Chatwani et al). 1992;166:598-600

Legislation
Folly, woodenheadedness, and the alluvial mind: presidential address (Bolton). 1992;166:1595-6

Leiomyoma
Insulin-like growth factor I and II binding in human myometrium and leiomyomas (Chandrasekhar et al). 1992;166:64-9
Rapid growth of leiomyoma in patient receiving tamoxifen (Dilts et al). 1992;166:167-8
Treatment of uterine fibroids: current findings with gonadotropin-releasing hormone agonists (Adamson). 1992;166:746-51

Leiomyosarcoma
Deoxyribonucleic acid analysis by flow cytometry of uterine leiomyosarcomas and smooth muscle tumors of uncertain malignant potential (Peters et al). 1992;166:1646-54
Phase II trial of ifosfamide and mesna in leiomyosarcoma of the uterus: a gynecologic oncology group study (Sutton et al). 1992;166:556-9

Letters
Letters. 1992;166:263-9, 766-71, 1020-5, 1306-13, 1588-93, 1863-8

Leukemia, myeloid
Hydroxyurea and pregnancy (Tertian et al). 1992;166:1868 (Letter)
Leukocytes
Human vaginal leukocytes and the effects of vaginal fluid on lymphocyte and macrophage defense functions (Hill and Anderson). 1992;166:720-6
Leukocytes, mononuclear
Possible transplacental transmission of human papillomaviruses (Tseng et al). 1992;166:35-40
Leukotrienes
Influence of labor and oxytocin on in vitro leukotriene release by human fetal membranes and uterine decidua at term gestation (Pasetto et al). 1992;166:1500-6
Leuprolide
Treatment of uterine fibroids: current findings with gonadotropin-releasing hormone agonists (Adamson). 1992;166:746-51
Levonorgestrel
Contraceptive compliance with a levonorgestrel triphasic and a norethindrone monophasic oral contraceptive in adolescent patients (Woods et al). 1992;166:901-7
The effect of continuous subdermal levonorgestrel (Norplant) on carbohydrate metabolism (Konje et al). 1992;166:15-9
Levonorgestrel-releasing intrauterine contraceptive device; *see* **Intrauterine devices**
Leydig cells
Human ovarian 17-ketosteroid oxidoreductase: unique characteristics of the granulosa-luteal cell and stromal enzyme (Barbieri). 1992;166:1117-26
LH
Use of urinary luteinizing hormone immunoassays in the assessment of luteal function in infertile women (Corsan et al). 1992;166:41-6
Ligaments
Preoperative and postoperative analysis of site-specific pelvic support defects in 81 women treated with sacrospinous ligament suspension and pelvic reconstruction (Shull et al). 1992;166:1764-71
Prophylactic sacrospinous fixation discouraged (Scotti) (Letter); (Cruikshank) (Reply). 1992;166:1022-3
Lipids
Comparison of transdermal and oral estrogen/progestin replacement therapy: effects on serum lipids and lipoproteins (Crook et al). 1992;166:950-5
Lipid and apolipoprotein abnormalities in hirsute women. I. The association with insulin resistance (Wild et al). 1992;166:1191-7
Lipoproteins
Comparison of transdermal and oral estrogen/progestin replacement therapy: effects on serum lipids and lipoproteins (Crook et al). 1992;166:950-5
Lipoproteins, LDL
Lp(a) lipoprotein: relationship to cardiovascular disease risk factors, exercise, and estrogen (Lobo et al). 1992;166:1182-90
Low density lipoproteins; *see* **Lipoproteins, LDL**
Lung, growth and development
Mimicking low amniotic pressure by chronic pharyngeal drainage does not impair lung development in fetal sheep (Fisk et al). 1992;166:991-6
Lung diseases
Serial thoracic versus abdominal circumference ratios for the prediction of pulmonary hypoplasia in premature rupture of the membranes remote from term (D'Alton et al). 1992;166:658-63
Luteal phase
Gonadotropin and ovarian hormone dynamics in luteal phase defects (Alexander et al). 1992;166:652-7
Use of urinary luteinizing hormone immunoassays in the assessment of luteal function in infertile women (Corsan et al). 1992;166:41-6
Luteinizing hormone; *see* **LH**
Lymph node excision
Laparoscopic radical hysterectomy with paraaortic and pelvic node dissection (Nezhat et al). 1992;166:864-5
Lymphocytes
Human vaginal leukocytes and the effects of vaginal fluid on lymphocyte and macrophage defense functions (Hill and Anderson). 1992;166:720-6

M

Macrophage colony-stimulating factor
Serum levels of macrophage colony-stimulating factor in patients with ovarian cancer undergoing second-look laparotomy (Elg et al). 1992;166:134-7
Macrophages
Human vaginal leukocytes and the effects of vaginal fluid on lymphocyte and macrophage defense functions (Hill and Anderson). 1992;166:720-6
Macrosomic fetus; *see* **Fetal macrosomia**
Magnesium
Oral magnesium and the prevention of preterm labor in a high-risk group of patients (Martin et al). 1992;166:144-7
Magnesium sulfate
Anticonvulsant effects of magnesium sulfate on hippocampal seizures: therapeutic implications in preeclampsia-eclampsia (Cotton et al). 1992;166:1127-36
Magnesium sulfate is an unfit anticonvulsant in eclampsia (Luan) (Letter); (Sibai) (Reply). 1992;166:1588
Transient symptomatic subendocardial ischemia during intravenous magnesium sulfate tocolytic therapy (Sherer et al). 1992;166:33-5
Magnetics
Magnetic cell sorting and the transferrin receptor as potential means of prenatal diagnosis from maternal blood (Gänshirt-Ahlert et al). 1992;166:1350-5
Malpractice
At last: an objective observation (Morton). 1992;166:1312 (Letter)
Mass screening
The California Maternal Serum α-Fetoprotein Screening Program: the role of ultrasonography in the detection of spina bifida (Platt et al). 1992;166:1328-9
A comprehensive program for cervical cancer detection and management (Benedet et al). 1992;166:1254-9
Ovarian cancer screening (Gosink) (Letter); (Creasman and DiSaia) (Reply). 1992;166:1591-3
Maternal blood; *see* **Blood**
Maternal mortality
Fatal maternal laryngeal papillomatosis in pregnancy: a case report (Helmrich et al). 1992;166:524-5
Main clinical types and subtypes of eclampsia (López-Llera). 1992;166:4-9
Mathematical model; *see* **Models, theoretical**
Mathematics
Derivation of new mathematic formulas for determining

Mathematics—cont'd
whether a D-positive father is heterozygous or homozygous for the D antigen (Kanter). 1992;166:61-3
May-Hegglin anomaly; *see* **Blood platelet disorders**
Meconium
Elective induction versus spontaneous labor: a retrospective study of complications and outcome (Macer et al). 1992;166:1690-7
Erythromycin, motilin, and meconium (Danielian) (Letter); (Nugent) (Reply). 1992;166:767-8
Meconium aspiration syndrome: reflections on a murky subject (Katz and Bowes). 1992;166:171-83 (Curr. dev.)
Medical staff
Leadership qualities of obstetrics and gynecology department chairmen of United States medical schools (Bates and Blackhurst). 1992;166:1102-16
Mefenamic acid
Effects of mefenamic acid on menstrual hemostasis in essential menorrhagia (van Eijkeren et al). 1992;166:1419-28
Menopause
The benefits and risks of hormone replacement therapy: an epidemiologic overview (Harlap). 1992;166:1986-92
Introduction to steroids in the menopause (Samsioe). 1992;166:1980-5
Postmenopausal steroid replacement with micronized dehydroepiandrosterone: preliminary oral bioavailability and dose proportionality studies (Buster et al). 1992;166:1163-70
A reevaluation of estrogen status in postmenopausal women who smoke (Cassidenti et al). 1992;166:1444-8
The role of progestins in hormone replacement therapy (Lobo). 1992;166:1997-2004
Use of two types of estradiol-releasing skin patches for menopausal patients in a tropical climate (McCarthy et al). 1992;166:2005-10
Menopause, premature
Early menopause in long-term survivors of cancer during adolescence (Byrne et al). 1992;166:788-93
Menorrhagia
Effects of mefenamic acid on menstrual hemostasis in essential menorrhagia (van Eijkeren et al). 1992;166:1419-28
Hysteroscopic myometrial biopsy: its use in diagnosing adenomyosis and its clinical application (McCausland). 1992;166:1619-28
Tubal sterilization and risk of subsequent hospital admission for menstrual disorders (Shy et al). 1992;166:1693-706
Menstrual cycle
Ultrastructure of the microvasculature in the human endometrium throughout the normal menstrual cycle (Roberts et al). 1992;166:1393-406
Menstruation disorders
Effects of mefenamic acid on menstrual hemostasis in essential menorrhagia (van Eijkeren et al). 1992;166:1419-28
Tubal sterilization and risk of subsequent hospital admission for menstrual disorders (Shy et al). 1992;166:1698-706
Mental retardation
Maternal phenylketonuria collaborative study, obstetric aspects and outcome: the first 6 years (Platt et al). 1992;166:1150-62
Mentors
Leadership qualities of obstetrics and gynecology department chairmen of United States medical schools (Bates and Blackhurst). 1992;166:1102-16
2-Mercaptoethanesulfonate
Phase II trial of ifosfamide and mesna in leiomyosarcoma of the uterus: a gynecologic oncology group study (Sutton et al). 1992;166:556-9
Messenger ribonucleic acid; *see* **RNA, messenger**
Met-enkephalin; *see* **Enkephalins**
Metronidazole
Incidence of pelvic inflammatory disease after first-trimester legal abortion in women with bacterial vaginosis after treatment with metronidazole: a double-blind, randomized study (Larsson et al). 1992;166:100-3
Vaginal Po_2 in healthy women and in women infected with *Trichomonas vaginalis*: potential implications for metronidazole therapy (Rashad et al). 1992;166:620-4
Metrorrhagia
Tubal sterilization and risk of subsequent hospital admission for menstrual disorders (Shy et al). 1992;166:1698-706
Midtrimester; *see* **Pregnancy trimester, second**
Mifepristone
Natural killer cell activity from pregnant subjects is modulated by RU 486 (Hansen et al). 1992;166:87-90
Milrinone
The maternal and fetal effects of milrinone and dopamine in normotensive pregnant ewes (Santos et al). 1992;166:257-62
Miscarriage; *see* **Abortion**
Models, theoretical
A model-based prediction for transvaginal ultrasonographic identification of early intrauterine pregnancy (Shapiro et al). 1992;166:1495-500
Moniliasis, vulvovaginal
Cellular immunity of patients with recurrent or refractory vulvovaginal moniliasis (Fong et al). 1992;166:887-90
Monocytes
Stimulation of ovarian tumor cell proliferation with monocyte products, including interleukin-α, interleukin-6, and tumor necrosis factor-α (Wu et al). 1992;166:997-1007
Mononuclear cells; *see* **Leukocytes, mononuclear**
Morals
Contraceptive prevalence, reproductive health, and international morality (Diczfalusy). 1992;166:1037-43
Morbidity
Acute childbirth morbidity: its measurement using hospital charges (Hage et al). 1992;166:1853-62
Influence of alcohol intake on postoperative morbidity after hysterectomy (Felding et al). 1992;166:667-70
Neonatal morbidity according to gestational age and birth weight from five tertiary care centers in the United States, 1983 through 1986 (Robertson et al). 1992;166:1629-45
Radical hysterectomy in the elderly patient: analysis of morbidity (Fuchtner et al). 1992;166:593-7
Motherhood
Abortion or motherhood, suicide and madness (Ryan). 1992;166:1029-36
Motilin
Erythromycin, motilin, and meconium (Danielian) (Letter); (Nugent) (Reply). 1992;166:767-8
Muscle, smooth
Deoxyribonucleic acid analysis by flow cytometry of uterine leiomyosarcomas and smooth muscle tumors of uncertain malignant potential (Peters et al). 1992;166:1646-54

Muscle, smooth, vascular
Endothelium-derived relaxing factor and indomethacin-sensitive contracting factor alter arterial contractile responses to thromboxane during pregnancy (Weiner et al). 1992;166:1171-81
Lack of reactivity of uterine arteries from patients with obstetric hemorrhage (Nelson and Suresh). 1992;166:1436-43
Myeloid leukemia; *see* **Leukemia, myeloid**
Myocardial ischemia; *see* **Ischemia**
Myoma
Insulin-like growth factor I and II binding in human myometrium and leiomyomas (Chandrasekhar et al). 1992; 166:64-9
Myometrium
Hysteroscopic myometrial biopsy: its use in diagnosing adenomyosis and its clinical application (McCausland). 1992;166:1619-28
Insulin-like growth factor I and II binding in human myometrium and leiomyomas (Chandrasekhar et al). 1992; 166:64-9
Oxytocin given in a pulsatile manner to the ewe at 120 to 140 days' gestational age increases fetal sheep plasma cortisol (Sadowsky et al). 1992;166:200-5
The presence of platelet-activating factor binding sites in human myometrium and their role in uterine contraction (Zhu et al). 1992;166:1222-7
Myotonia atrophica
Hydrops fetalis associated with congenital myotonic dystrophy (Afifi et al). 1992;166:929-30
Myotonic dystrophy; *see* **Myotonia atrophica**

N

Nafarelin
Bioavailability of nafarelin in healthy volunteers (Chaplin). 1992;166:762-5
Gonadotropin-releasing hormone analogs: update on new findings (Henzl). 1992;166:757-61
Nafarelin in the management of endometriosis: quality of life assessment (Burry). 1992;166:735-9
Treatment of uterine fibroids: current findings with gonadotropin-releasing hormone agonists (Adamson). 1992;166:746-51
Natriuretic peptides, atrial
Low-dose infusion of atrial natriuretic peptide in the conscious guinea pig increases blood flow to the placenta of growth-retarded fetuses (Jansson). 1992;166: 213-8
Natural killer cells; *see* **Killer cells, natural**
Near-infrared spectroscopy; *see* **Spectrum analysis**
Necrosis
Necrotizing fasciitis of the vulva (Stephenson et al). 1992;166:1324-7
Neisseria gonorrhoeae
Preterm premature rupture of membranes: results of expectant management in patients with cervical cultures positive for group B streptococcus or *Neisseria gonorrhoeae* (Maxwell and Watson). 1992;166:945-9
Nematode infections
Nematode infections: Is it wise to withhold medical treatment during pregnancy? I. Biliary complications (Vullar L. et al). 1992;166:549-50
Neonate; *see* **Infant, newborn**
Neoplasm metastasis
Ovarian metastases in stage IB carcinoma of the cervix: a Gynecologic Oncology Group study (Sutton et al). 1992;166:50-3
Neoplasms
Early menopause in long-term survivors of cancer during adolescence (Byrne et al). 1992;166:788-93
Neural network
The use of neural network for the ultrasonographic estimation of fetal weight in the macrosomic fetus (Farmer et al). 1992;166:1467-72
Neural tube defects
The California Maternal Serum α-Fetoprotein Screening Program: the role of ultrasonography in the detection of spina bifida (Platt et al). 1992;166:1328-9
Nitric oxide
Attenuation of the vasoconstrictor effects of thromboxane and endothelin by nitric oxide in the human fetal-placental circulation (Myatt et al). 1992;166:224-30
Nω-Nitro-L-arginine, and inhibitor of nitric oxide synthesis, increases blood pressure in rats and reverses the pregnancy-induced refractoriness to vasopressor agents (Molnár and Hertelendy). 1992;166:1560-7
Nitroglycerin; *see* **Glyceryl trinitrate**
Norethindrone
Contraceptive compliance with a levonorgestrel triphasic and a norethindrone monophasic oral contraceptive in adolescent patients (Woods et al). 1992;166:901-7
Gonadotropin-releasing hormone agonists: strategies for managing the hypoestrogenic effects of therapy (Judd). 1992;166:752-6
Gonadotropin-releasing hormone analogs: update on new findings (Henzl). 1992;166:757-61
Norgestimate
The efficacy and tolerability of norgestimate/ethinyl estradiol (250 μg of norgestimate/35 μg of ethinyl estradiol): results of an open, multicenter study of 59,701 women (Runnebaum et al). 1992;166:1963-8
Norgestimate: a clinical overview of a new progestin (Bringer). 1992;166:1978-9
Norplant; *see* **Levonorgestrel**
Numerical analysis, computer-assisted
Numeric analysis of heart rate variation in intrauterine growth-retarded fetuses: a longitudinal study (Snijders et al). 1992;166:22-7
Nylidrin
Urinary excretion of prostacyclin and thromboxane metabolites in threatened preterm labor: effect of indomethacin and nylidrin (Kurki et al). 1992;166:150-4

O

Obstructive uropathy; *see* **Urinary tract, pathology**
Office visits
Pelvic inflammatory disease: trends in hospitalizations and office visits, 1979 through 1988 (Rolfs et al). 1992; 166:983-90
Oligohydramnios
Mimicking low amniotic pressure by chronic pharyngeal drainage does not impair lung development in fetal sheep (Fisk et al). 1992;166:991-6
Omentum
Omental graft made simple (Petty). 1992;166:1591 (Letter)
Oocytes
Criteria for the diagnosis of infertility (Kessopoulou et al) (Letter); (Aitken) (Reply). 1992;166:264-5

Oral administration; *see* **Administration, oral**
Oral contraceptives; *see* **Contraceptives, oral**
Osteoporosis
The effect of sex steroids on the skeleton in premenopausal women (Lindsay). 1992;166:1993-6
Low-dosage micronized 17β-estradiol prevents bone loss in postmenopausal women (Ettinger et al). 1992;166:1579-88
Prolonged effects of a novel, low-dosage continuous progestin–cyclic estrogen replacement program in postmenopausal women (Plunkett and Wolfe). 1992;166:117-21
Outcome of pregnancy; *see* **Pregnancy outcome**
Ovarian cysts
Giant ovarian cyst: case report (Zamora-Garza et al). 1992;166:1247-8
Oral contraceptive type and functional ovarian cysts (Lanes et al). 1992;166:956-61
Ovarian hyperstimulation
Effect of controlled ovarian hyperstimulation on pregnancy rates after intrauterine insemination (DiMarzo et al). 1992;166:1607-13
Ovarian neoplasms
Advanced epithelial ovarian carcinoma: long-term survival experience at the community hospital (Unzelman). 1992;166:1663-72
The cavitational ultrasonic surgical aspirator for cytoreduction in advanced ovarian cancer (Rose). 1992;166:843-6
Human monoclonal antibody recognizing an antigen associated with ovarian and other adenocarcinomas (Smith et al). 1992;166:634-45
Meta-analysis of surgery in advanced ovarian carcinoma: Is maximum cytoreductive surgery an independent determinant of prognosis? (Hunter et al). 1992;166:504-11
Ovarian cancer screening (Gosink) (Letter); (Creasman and DiSaia) (Reply). 1992;166:1591-3
Ovarian carcinoma of low malignant potential, infertility, and induction of ovulation: Is there a link? (Goldberg and Runowicz). 1992;166:853-4
Ovarian metastases in stage IB carcinoma of the cervix: a Gynecologic Oncology Group study (Sutton et al). 1992;166:50-3
Regulation of growth of normal ovarian epithelial cells and ovarian cancer cell lines by transforming growth factor-β (Berchuck et al). 1992;166:676-84
The safety of oral contraceptives: epidemiologic insights from the first 30 years (Grimes). 1992;166:1950-4
Serum levels of macrophage colony-stimulating factor in patients with ovarian cancer undergoing second-look laparotomy (Elg et al). 1992;166:134-7
Stimulation of ovarian tumor cell proliferation with monocyte products, including interleukin-α, interleukin-6, and tumor necrosis factor-α (Wu et al). 1992;166:997-1007
Ovary
The effect of benzo(a)pyrene on murine ovarian and corpora lutea volumes (Miller et al). 1992;166:1535-41
Human ovarian 17-ketosteroid oxidoreductase: unique characteristics of the granulosa-luteal cell and stromal enzyme (Barbieri). 1992;166:1117-26
Oviduct transport; *see* **Ovum transport**
Ovulation
Prevalence of out-of-phase endometrial biopsy specimens (Peters et al). 1992;166:1733-46
Ovulation induction
Ovarian carcinoma of low malignant potential, infertility, and induction of ovulation: Is there a link? (Goldberg and Runowicz). 1992;166:853-4
Ovum implantation
The effect of preovulatory peritoneal fluid from cases of endometriosis on murine in vitro fertilization, embryo development, oviduct transport, and implantation (Dodds et al). 1992;166:219-24
Ovum transport
The effect of preovulatory peritoneal fluid from cases of endometriosis on murine in vitro fertilization, embryo development, oviduct transport, and implantation (Dodds et al). 1992;166:219-24
Oxidized cellulose; *see* **Cellulose, oxidized**
Oxidoreductases
Human ovarian 17-ketosteroid oxidoreductase: unique characteristics of the granulosa-luteal cell and stromal enzyme (Barbieri). 1992;166:1117-26
Oxygen consumption
Changes in human fetal cerebral hemoglobin concentration and oxygenation during labor measured by near-infrared spectroscopy (Peebles et al). 1992;166:1369-73
Effects of chronic maternal anemia on systemic and uteroplacental oxygenation in near-term pregnant sheep (Delpapa et al). 1992;166:1007-12
Oxytocin
Does oxytocin augmentation increase perinatal risk in primigravid labor? (Cahill et al). 1992;166:847-50
Elective induction versus spontaneous labor: a retrospective study of complications and outcome (Macer et al). 1992;166:1690-7
Factors affecting the dose response to oxytocin for labor stimulation (Satin et al). 1992;166:1260-1
Influence of labor and oxytocin on in vitro leukotriene release by human fetal membranes and uterine decidua at term gestation (Pasetto et al). 1992;166:1500-6
Oxytocin given in a pulsatile manner to the ewe at 120 to 140 days' gestational age increases fetal sheep plasma cortisol (Sadowsky et al). 1992;166:200-5

P

P-glycoprotein; *see* **Glycoproteins**
Pacific Coast Obstetrical and Gynecological Society
Transactions of the fifty-eighth annual meeting of the Pacific Coast Obstetrical and Gynecological Society. 1992;166:1595-711
Pain
The resolution of chronic pelvic pain after normal laparoscopy findings (Baker and Symonds). 1992;166:835-6
Papanicolaou smear; *see* **Vaginal smears**
Papilloma
Fatal maternal laryngeal papillomatosis in pregnancy: a case report (Helmrich et al). 1992;166:524-5
Papillomaviruses
Oral folic acid supplementation for cervical dysplasia: a clinical intervention trial (Butterworth et al). 1992;166:803-9
Possible transplacental transmission of human papillomaviruses (Tseng et al). 1992;166:35-40
Superficial laser vulvectomy. V. Surgical debulking is enhanced by adjuvant systemic interferon (Reid et al). 1992;166:815-20
Paraaortic node dissection; *see* **Lymph node excision**
Parent-child relations
Attitudes toward reproduction in a nonpatient population (Wikman et al). 1992;166:121-6

Parturition; *see* **Labor**
Pathology
Examination of placentas by pathologists (Altshuler). 1992;166:1312 (Letter)
Patient compliance
Contraceptive compliance with a levonorgestrel triphasic and a norethindrone monophasic oral contraceptive in adolescent patients (Woods et al). 1992;166:901-7
Patient education
Training obstetric and family practice residents to give smoking cessation advice during prenatal care (Secker-Walker et al). 1992;166:1356-63
Pelvic abscess; *see* **Adnexitis**
Pelvic belts
An integrated therapy for peripartum pelvic instability: a study of the biomechanical effects of pelvic belts (Vleeming et al). 1992;166:1243-7
Pelvic inflammatory disease; *see* **Adnexitis**
Pelvic neoplasms
The clinical significance of thrombocytosis in women presenting with a pelvic mass (Chalas et al). 1992;166:974-7
Pelvic node dissection; *see* **Lymph node excision**
Pelvis
An integrated therapy for peripartum pelvic instability: a study of the biomechanical effects of pelvic belts (Vleeming et al). 1992;166:1243-7
Preoperative and postoperative analysis of site-specific pelvic support defects in 81 women treated with sacrospinous ligament suspension and pelvic reconstruction (Shull et al). 1992;166:1764-71
The resolution of chronic pelvic pain after normal laparoscopy findings (Baker and Symonds). 1992;166:835-6
Transvaginal ultrasonographic quantitative assessment of accumulated cul-de-sac fluid (Rosen et al). 1992;166:542-4
Perforated appendicitis; *see* **Appendicitis**
Periconception; *see* **Fertilization**
Pericytes
Ultrastructure of the microvasculature in the human endometrium throughout the normal menstrual cycle (Roberts et al). 1992;166:1393-406
Perineum
Vaginal injury resulting from sliding down a water chute (Niv et al). 1992;166:930-1
Peripheral blood; *see* **Blood**
Peritoneal fluid; *see* **Ascitic fluid**
Peritoneoscopy
Frontiers of operative laparoscopy: a review and critique of the evidence (Grimes). 1992;166:1062-71
Infertility and endometriosis: comparison of pregnancy outcomes with laparotomy versus laparoscopic techniques (Gant). 1992;166:1072-81
Laparoscopic radical hysterectomy with paraaortic and pelvic node dissection (Nezhat et al). 1992;166:864-5
The need for technology assessment in the reproductive sciences (McDonough). 1992;166:1082-90
Pelvic inflammatory disease: findings during inpatient treatment of clinically severe, laparoscopy-documented disease (Livengood et al). 1992;166:519-24
The resolution of chronic pelvic pain after normal laparoscopy findings (Baker and Symonds). 1992;166:835-6
Treatment of unruptured tubal pregnancy by laparoscopic instillation of hyperosmolar glucose solution (Lang et al). 1992;166:1378-81
Peritoneum
Comparison of the peritoneal cells elicited by oxidized regenerated cellulose (Interceed) and expanded polytetrafluoroethylene (Gore-Tex Surgical Membrane) in a murine model (Haney and Doty). 1992;166:1137-49
Peritonitis
Abruptio placentae associated with perforated appendicitis and generalized peritonitis (Yaron et al). 1992;166:14-5
Pessaries
A randomized trial of prostaglandin E_2 in a controlled-release vaginal pessary for cervical ripening at term (Witter et al). 1992;166:830-4
Phenylketonuria
Maternal phenylketonuria collaborative study, obstetric aspects and outcome: the first 6 years (Platt et al). 1992;166:1150-62
Placenta
Attenuation of the vasoconstrictor effects of thromboxane and endothelin by nitric oxide in the human fetal-placental circulation (Myatt et al). 1992;166:224-30
Doppler ultrasonographic features of the developing placental circulation: correlation with anatomic findings (Jauniaux et al). 1992;166:585-7
Examination of placentas by pathologists (Altshuler). 1992;166:1312 (Letter)
In the rhesus monkey placental retention after fetectomy at 121 to 130 days' gestation outlasts the normal duration of pregnancy (Nathanielsz et al). 1992;166:1529-35
Low-dose infusion of atrial natriuretic peptide in the conscious guinea pig increases blood flow to the placenta of growth-retarded fetuses (Jansson). 1992;166:213-8
Possible transplacental transmission of human papillomaviruses (Tseng et al). 1992;166:35-40
Placenta diseases
Infarction of placental chorioangioma and associated regression of hydrops fetalis (Hsieh and Soong) (Letter); (Chazotte et al) (Reply). 1992;166:1306
The relationship between acute inflammatory lesions of the preterm placenta and amniotic fluid microbiology (Romero et al). 1992;166:1382-8
Placental hormones
Elevated maternal plasma corticotropin-releasing hormone levels in pregnancies complicated by preterm labor (Warren et al). 1992;166:1198-207
Placental lactogen
Partial hydatidiform moles have impaired differentiated function (human chorionic gonadotropin and human placental lactogen secretion) in response to epidermal growth factor and 8-bromo-cyclic adenosine monophosphate (Morrish et al). 1992;166:160-6
Placental proteins; *see* **Pregnancy proteins**
Planned pregnancy; *see* **Family planning**
Plasma
Elevated maternal plasma corticotropin-releasing hormone levels in pregnancies complicated by preterm labor (Warren et al). 1992;166:1198-207
Elevated plasma Met-enkephalin levels in the human newborn are a poor indicator of perinatal stress (Martinez et al). 1992;166:1429-35
Plasma exchange
Intravenous immunoglobulins in postpartum, persistently severe HELLP syndrome: A safe alternative to plasma exchange? (Pourrat et al) (Letter); (Files and Martin) (Reply). 1992;166:766

Plasminogen activators
Direct inhibition of proteases and cervical plasminogen activator by antibiotics (Milwidsky et al). 1992;166:506-12
Platelet activating factor
Effects of platelet-activating factor on prostaglandin E_2 production by intact fetal membranes (Morris et al). 1992;166:1228-31
The presence of platelet-activating factor binding sites in human myometrium and their role in uterine contraction (Zhu et al). 1992;166:1222-7
Platelet activation
Platelet activation and vascular damage in gestational hypertension (Ballegeer et al). 1992;166:629-33
Platelet transfusion; *see* **Blood transfusion, intrauterine**
Platelets; *see* **Blood platelets**
Poiseuille equation
Applicability of the Poiseuille equation to umbilical artery velocimetry (Degani) (Letter); (Wright and Ridgway) (Reply). 1992;166:766-7
Polycyclic hydrocarbons
The effect of benzo(a)pyrene on murine ovarian and corpora lutea volumes (Miller et al). 1992;166:1535-41
Polycythemia
Fetal polycythemia and thrombocytopenia in pregnancies complicated by maternal diabetes mellitus (Salvesen et al). 1992;166:1287-92
Polyhydramnios
Therapeutic amniocentesis in twin-twin transfusion syndrome appearing in the second trimester of pregnancy (Saunders et al). 1992;166:820-4
Polymerase chain reaction
Magnetic cell sorting and the transferrin receptor as potential means of prenatal diagnosis from maternal blood (Gänshirt-Ahlert et al). 1992;166:1350-5
Possible transplacental transmission of human papillomaviruses (Tseng et al). 1992;166:35-40
Polytetrafluoroethylene
Comparison of the peritoneal cells elicited by oxidized regenerated cellulose (Interceed) and expanded polytetrafluoroethylene (Gore-Tex Surgical Membrane) in a murine model (Haney and Doty). 1992;166:1137-49
Polyunsaturated fatty acids; *see* **Fatty acids, polyunsaturated**
Population
Population differences of fetal biophysical and behavioral characteristics (Johnson et al). 1992;166:138-42
Postmenopause; *see* **Menopause**
Postterm infant; *see* **Infant, postmature**
Pre-eclampsia
Abnormal 1,25-dihydroxyvitamin D metabolism in preeclampsia (August et al). 1992;166:1295-9
Anticonvulsant effects of magnesium sulfate on hippocampal seizures: therapeutic implications in preeclampsia-eclampsia (Cotton et al). 1992;166:1127-36
Eclampsia. VII. Pregnancy outcome after eclampsia and long-term prognosis (Sibai et al). 1992;166:1757-63
The function of elevated plasma fibronectin in preeclampsia (Brubaker et al). 1992;166:526-31
Immunoreactive circulating endothelin-1 in normal and hypertensive pregnancies (Schiff et al). 1992;166:624-8
Interrelationship and clinical significance of increased resistance in the uterine arteries in patients with hypertension or preeclampsia or both (Kofinas et al). 1992;166:601-6
Intravenous immunoglobulins in postpartum, persistently severe HELLP syndrome: A safe alternative to plasma exchange? (Pourrat et al) (Letter); (Files and Martin) (Reply). 1992;166:766
Magnesium sulfate is an unfit anticonvulsant in eclampsia (Luan) (Letter); (Sibai) (Reply). 1992;166:1588
More on early detection of preeclampsia (Ales) (Letter); (Sibai) (Reply). 1992;166:1306-8
The natural history of thrombocytopenia associated with preeclampsia (Catanzarite). 1992;166:770-1 (Letter)
Plasma endothelin levels in preeclampsia: elevation and correlation with uric acid levels and renal impairment (Clark et al). 1992;166:962-8
Platelet activation and vascular damage in gestational hypertension (Ballegeer et al). 1992;166:629-33
Polyunsaturated fatty acids in preeclampsia (Sanjurjo et al) (Letter); (Wang et al) (Reply). 1992;166:1023-4
Preeclampsia, von Willebrand factor antigen, and endothelial cells (Blann) (Letter); (Taylor et al) (Reply). 1992;166:769-70
Predictive value of tests
Amniotic fluid glucose and intraamniotic infection: sensitivity, specificity, and predictive values (Gonen) (Letter); (Kirshon) (Reply). 1992;166:1863-4
Receiver-operator characteristic, efficiency analysis, and predictive value of serum progesterone concentration as a test for abnormal gestations (Cowan et al). 1992;166:1729-37
Unexplained elevated maternal serum α-fetoprotein is not predictive of adverse perinatal outcome in an indigent urban population (Phillips et al). 1992;166:978-82
Prednisone
Repeated fetal losses associated with antiphospholipid antibodies: a collaborative randomized trial comparing prednisone with low-dose heparin treatment (Cowchock et al). 1992;166:1318-23
Pregnancy, blood
The blood pressure response to infusions of angiotensin II during normal pregnancy: relation to plasma angiotensin II concentration, serum progesterone level, and mean platelet volume (Ito et al). 1992;166:1249-53
Endothelium-derived relaxing factor and indomethacin-sensitive contracting factor alter arterial contractile responses to thromboxane during pregnancy (Weiner et al). 1992;166:1171-81
Nω-Nitro-L-arginine, and inhibitor of nitric oxide synthesis, increases blood pressure in rats and reverses the pregnancy-induced refractoriness to vasopressor agents (Molnár and Hertelendy). 1992;166:1560-7
Pregnancy, drug effects
Anticancer drugs during pregnancy: Are we able to discard them? (Kim et al) (Letter); (van der Zee et al) (Reply). 1992;166:265-6
The maternal and fetal effects of milrinone and dopamine in normotensive pregnant ewes (Santos et al). 1992;166:257-62
Routine urine drug screening at the first prenatal visit (Colmorgen et al). 1992;166:588-90
Pregnancy, ectopic
Frontiers of operative laparoscopy: a review and critique of the evidence (Grimes). 1992;166:1062-71
Laboratory and clinical comparison of a rapid versus a classic progesterone radioimmunoassay for use in determining abnormal and ectopic pregnancies (Peterson et al). 1992;166:562-6
Pregnancy, epidemiology
Effect of controlled ovarian hyperstimulation on pregnancy

rates after intrauterine insemination (DiMarzo et al). 1992;166:1607-13
Selection bias in in vitro fertilization programs (Hershlag et al). 1992;166:1-3 (Clin. opinion)

Pregnancy, immunology
Natural killer cell activity from pregnant subjects is modulated by RU 486 (Hansen et al). 1992;166:87-90

Pregnancy, multiple
Breech extraction of low-birth-weight second twins: Can cesarean section be justified? (Davison et al). 1992; 166:497-502
Triplet pregnancy involving complete hydatidiform mole and two fetuses: genetic analysis by deoxyribonucleic acid fingerprint (Azuma et al). 1992;166:664-7
The Zavanelli maneuver applied to locked twins (Swartjes et al). 1992;166:532

Pregnancy, physiology
Arterial pressure response to maximal isometric exercise in pregnant women (Lotgering et al). 1992;166:538-42
Describing and interpreting 24-hour blood pressure patterns in physiologic pregnancy (Cugini et al). 1992; 166:54-60
Doppler ultrasonographic features of the developing placental circulation: correlation with anatomic findings (Jauniaux et al). 1992;166:585-7
Long-term acid-base measurements in the fetal and maternal baboon (Daniel et al). 1992;166:707-12
Maternal and fetal cardiovascular responses to strenuous bicycle exercise (van Doorn et al). 1992;166:854-9
Prostaglandin- or endothelium-mediated vasodilation is not involved in the blunted responses of blood vessels to vasoconstrictors in pregnant rats (St-Louis and Sicotte). 1992;166:684-92

Pregnancy, psychology
Depressive symptoms in women in the 6 months after miscarriage (Neugebauer et al). 1992;166:104-9

Pregnancy, tubal
Treatment of unruptured tubal pregnancy by laparoscopic instillation of hyperosmolar glucose solution (Lang et al). 1992;166:1378-81

Pregnancy complications
Cervical stenosis in pregnancy: a complication of cryotherapy in diethylstilbestrol-exposed women (Kalstone). 1992;166:502-3
Eosinophilic cystitis during pregnancy (Chamberlin). 1992; 166:28-9
Hospitalization for pregnancy complications, United States, 1986 and 1987 (Franks et al). 1992;166:1339-44
Laboratory and clinical comparison of a rapid versus a classic progesterone radioimmunoassay for use in determining abnormal and ectopic pregnancies (Peterson et al). 1992;166:562-6
Nonsurgical management of penetrating uterine trauma in pregnancy: a case report (Grubb). 1992;166:583-4
A randomized, placebo-controlled trial of betamethasone for the prevention of respiratory distress syndrome at 24 to 28 weeks' gestation (Garite et al). 1992;166:646-51
Spontaneous abortion and subsequent adverse birth outcomes (Thom et al). 1992;166:111-6
Successive pregnancies complicated by idiopathic sideroblastic anemia (Barton et al). 1992;166:576-7

Pregnancy complications, cardiovascular
Abnormal 1,25-dihydroxyvitamin D metabolism in preeclampsia (August et al). 1992;166:1295-9
Familial occurrence of thrombotic thrombocytopenic purpura in two sisters during pregnancy (Wiznitzer et al). 1992;166:20-1
Immunoreactive circulating endothelin-1 in normal and hypertensive pregnancies (Schiff et al). 1992;166: 624-8
Interrelationship and clinical significance of increased resistance in the uterine arteries in patients with hypertension or preeclampsia or both (Kofinas et al). 1992; 166:601-6
Main clinical types and subtypes of eclampsia (López-Llera). 1992;166:4-9
Progression of diabetic retinopathy in pregnancy: association with hypertension in pregnancy (Rosenn et al). 1992;166:1214-8
Transient symptomatic subendocardial ischemia during intravenous magnesium sulfate tocolytic therapy (Sherer et al). 1992;166:33-5
Uterine and umbilical flow velocity waveforms in normotensive and hypertensive subjects during the angiotensin II sensitivity test (Erkkola and Pirhonen). 1992;166: 910-6

Pregnancy complications, hematologic
Acute posttraumatic fetal anemia treated with fetal intravascular transfusion (Del Valle et al). 1992;166:127-9
Angiographic embolization in the management of hemorrhagic complications of pregnancy (Gilbert et al). 1992;166:493-7
Effects of chronic maternal anemia on systemic and uteroplacental oxygenation in near-term pregnant sheep (Delpapa et al). 1992;166:1007-12
Hydroxyurea and pregnancy (Tertian et al). 1992;166:1868 (Letter)
Lack of reactivity of uterine arteries from patients with obstetric hemorrhage (Nelson and Suresh). 1992;166:1436-43
May-Hegglin anomaly: a rare case of maternal thrombocytopenia in pregnancy (Chatwani et al). 1992;166:143-4
Successive pregnancies complicated by idiopathic sideroblastic anemia (Barton et al). 1992;166:576-7

Pregnancy complications, infectious
Abruptio placentae associated with perforated appendicitis and generalized peritonitis (Yaron et al). 1992;166:14-5
Characteristics of three vaginal flora patterns assessed by Gram stain among pregnant women (Hillier et al). 1992;166:938-44
Endothelin-1 and endothelin-2 levels are increased in the amniotic fluid of women with preterm labor and microbial invasion of the amniotic cavity (Romero et al). 1992;166:95-9
Eradication of *Ureaplasma urealyticum* from the amniotic fluid with transplacental antibiotic treatment (Romero et al). 1992;166:618-20
Erythromycin therapy in preterm premature rupture of the membranes: a prospective, randomized trial of 220 patients (Mercer et al). 1992;166:794-802
Infection and labor. VII. Microbial invasion of the amniotic cavity in spontaneous rupture of membranes at term (Romero et al). 1992;166:129-33
Is trichomoniasis often associated with bacterial vaginosis in pregnant adolescents? (James et al). 1992;166:859-63
The mechanisms of preterm labor: common genital tract pathogens do not metabolize arachidonic acid to prostaglandins or to other eicosanoids (Bennett and Elder). 1992;166:1541-5
Nematode infections: Is it wise to withhold medical treat-

Pregnancy complications, infectious—cont'd
ment during pregnancy? I. Biliary complications (Villar L. and Sibai). 1992;166:549-50
Possible transplacental transmission of human papillomaviruses (Tseng et al). 1992;166:35-40
Prenatal diagnosis of fetal cytomegalovirus infection (Lamy et al). 1992;166:91-4
Preterm premature rupture of membranes: results of expectant management in patients with cervical cultures positive for group B streptococcus or *Neisseria gonorrhoeae* (Maxwell and Watson). 1992;166:945-9
The relationship between acute inflammatory lesions of the preterm placenta and amniotic fluid microbiology (Romero et al). 1992;166:1382-8
A review of premature birth and subclinical infection (Gibbs et al). 1992;166:1515-28 (Curr. dev.)
Severe anti-C hemolytic disease of the newborn (Bowman et al). 1992;166:1239-43
What is the prognosis for congenital cytomegalovirus infection? (Binder). 1992;166:1591 (Letter)

Pregnancy complications, neoplastic
Anticancer drugs during pregnancy: Are we able to discard them? (Kim et al) (Letter); (van der Zee et al) (Reply). 1992;166:265-6
Fatal maternal laryngeal papillomatosis in pregnancy: a case report (Helmrich et al). 1992;166:524-5
Maternal and fetal outcome after breast cancer in pregnancy (Zemlickis et al). 1992;166:781-7

Pregnancy in adolescence
Is trichomoniasis often associated with bacterial vaginosis in pregnant adolescents? (James et al). 1992;166:859-63

Pregnancy in diabetes
The Diabetes in Early Pregnancy Study: changes in cholesterol, triglycerides, body weight, and blood pressure (Peterson et al). 1992;166:513-8
Fetal polycythemia and thrombocytopenia in pregnancies complicated by maternal diabetes mellitus (Salvesen et al). 1992;166:1287-92
Impairment of counterregulatory hormone responses to hypoglycemia in pregnant women with insulin-dependent diabetes mellitus (Diamond et al). 1992;166:70-7
Infertility and pregnancy outcome in an unselected group of women with insulin-dependent diabetes mellitus (Kjaer et al). 1992;166:1412-8
Maternal glucose intolerance and the subcutaneous terbutaline pump (Lindenbaum et al). 1992;166:925-8
Progression of diabetic retinopathy in pregnancy: association with hypertension in pregnancy (Rosenn et al). 1992;166:1214-8

Pregnancy maintenance
Diagnosis of cervical change in pregnancy by means of transvaginal ultrasonography (Joffe et al). 1992;166:896-900
Erythromycin therapy in preterm premature rupture of the membranes: a prospective, randomized trial of 220 patients (Mercer et al). 1992;166:794-802

Pregnancy outcome
Drug use or inadequate prenatal care? Adverse pregnancy outcome in an urban setting (Broekhuizen et al). 1992;166:1747-56
Early amniocentesis: outcome, risks, and technical problems at ≤12.8 weeks (Hanson et al). 1992;166:1707-11
Eclampsia. VII. Pregnancy outcome after eclampsia and long-term prognosis (Sibai et al). 1992;166:1757-63
Elective induction versus spontaneous labor: a retrospective study of complications and outcome (Macer et al). 1992;166:1690-7
Impact of histocompatibility antigens on pregnancy outcome (Eroglu et al). 1992;166:1354-9
Infertility and endometriosis: comparison of pregnancy outcomes with laparotomy versus laparoscopic techniques (Gant). 1992;166:1072-81
Infertility and pregnancy outcome in an unselected group of women with insulin-dependent diabetes mellitus (Kjaer et al). 1992;166:1412-8
Maternal phenylketonuria collaborative study, obstetric aspects and outcome: the first 6 years (Platt et al). 1992;166:1150-62
Rates and outcomes of planned pregnancy after use of Norplant capsules, Norplant II rods, or levonorgestrel-releasing or copper TCu 380Ag intrauterine contraceptive devices (Sivin et al). 1992;166:1208-13
Reproductive outcome in women with recurrent spontaneous abortions of alloimmune and autoimmune causes: preconception versus postconception treatment (Kwak et al). 1992;166:1787-98
Unexplained elevated maternal serum α-fetoprotein is not predictive of adverse perinatal outcome in an indigent urban population (Phillips et al). 1992;166:978-82

Pregnancy proteins
Transforming growth factor-α and epidermal growth factor messenger ribonucleic acid and protein levels in human placentas from early, mid, and late gestation (Bissonnette et al). 1992;166:192-9

Pregnancy tests
A model-based prediction for transvaginal ultrasonographic identification of early intrauterine pregnancy (Shapiro et al). 1992;166:1495-500

Pregnancy trimester, first
Changes in human platelet angiotensin II binding sites associated with early pregnancy (Baker et al). 1992;166:255-6
Embryoscopy: a closer look at first-trimester diagnosis and treatment (Reece et al). 1992;166:775-80 (Clin. opinion)
Intracerebral, aortic, and umbilical artery flow velocity waveforms in the late-first-trimester fetus (Wladimiroff et al). 1992;166:46-9

Pregnancy trimester, second
Maternal serum α-fetoprotein, β-human chorionic gonadotropin, and unconjugated estriol levels in midtrimester trisomy 18 pregnancies (Greenberg et al). 1992;166:1388-92
Renal autoregulation in midterm and late-pregnant rats (Reckelhoff et al). 1992;166:1546-50
Therapeutic amniocentesis in twin-twin transfusion syndrome appearing in the second trimester of pregnancy (Saunders et al). 1992;166:820-4

Pregnancy trimester, third
Renal autoregulation in midterm and late-pregnant rats (Reckelhoff et al). 1992;166:1546-50

Premature labor; *see* **Labor, premature**

Premature rupture of membranes; *see* **Fetal membranes, premature rupture**

Prenatal care
Drug use or inadequate prenatal care? Adverse pregnancy outcome in an urban setting (Broekhuizen et al). 1992;166:1747-56
Routine urine drug screening at the first prenatal visit (Colmorgen et al). 1992;166:538-90

Suffer the little children: presidential address (Youngblood). 1992;166:1712-6
Training obstetric and family practice residents to give smoking cessation advice during prenatal care (Secker-Walker et al). 1992;166:1356-63
Prenatal diagnosis; *see also* **Ultrasonography, prenatal**
Chorionic villus sampling for fetal Rh typing: clinical implications (Kickler et al). 1992;166:1407-11
Early amniocentesis: outcome, risks, and technical problems at ≤12.8 weeks (Hanson et al). 1992;166:1707-11
Embryoscopy: a closer look at first-trimester diagnosis and treatment (Reece et al). 1992;166:775-80 (Clin. opinion)
Fetal echocardiography: accuracy and limitations in a population at high and low risk for heart defects (Bromley et al). 1992;166:1473-81
Fetal urine biochemistry in the assessment of obstructive uropathy (Nicolaides et al). 1992;166:932-7
First report: telemetry-assisted ambulatory nonstress test (Collins). 1992;166:1020-1 (Letter)
Magnetic cell sorting and the transferrin receptor as potential means of prenatal diagnosis from maternal blood (Gänshirt-Ahlert et al). 1992;166:1350-5
Maternal serum α-fetoprotein, β-human chorionic gonadotropin, and unconjugated estriol levels in midtrimester trisomy 18 pregnancies (Greenberg et al). 1992;166:1388-92
Percutaneous umbilical blood sampling: results from a multicenter collaborative registry (Hickok et al). 1992;166:1614-8
Prenatal diagnosis of autosomal recessive polycystic kidney disease: variable outcome within one family (Barth et al). 1992;166:560-7
Prenatal diagnosis of fetal cytomegalovirus infection (Lamy et al). 1992;166:91-4
Prognosis in fetal diaphragmatic hernia (Sharland et al). 1992;166:9-13
Receiver-operator characteristic, efficiency analysis, and predictive value of serum progesterone concentration as a test for abnormal gestations (Cowan et al). 1992;166:1729-37
Serial thoracic versus abdominal circumference ratios for the prediction of pulmonary hypoplasia in premature rupture of the membranes remote from term (D'Alton et al). 1992;166:658-63
What is the prognosis for congenital cytomegalovirus infection? (Binder). 1992;166:1591 (Letter)
Prepubertal girl; *see* **Child**
Presidential address
Presidential address. 1992;166:1595-6, 1712-6
Preterm infant; *see* **Infant, premature**
Preterm labor; *see* **Labor, premature**
Progestational hormones
The benefits and risks of hormone replacement therapy: an epidemiologic overview (Harlap). 1992;166:1986-92
Clinical and metabolic considerations of long-term oral contraceptive use (Godsland et al). 1992;166:1955-63
Comparison of transdermal and oral estrogen/progestin replacement therapy: effects on serum lipids and lipoproteins (Crook et al). 1992;166:950-5
The effect of sex steroids on the skeleton in premenopausal women (Lindsay). 1992;166:1993-6
The efficacy and tolerability of norgestimate/ethinyl estradiol (250 μg of norgestimate/35 μg of ethinyl estradiol): results of an open, multicenter study of 59,701 women (Runnebaum et al). 1992;166:1963-8
Hormone treatment of endometriosis: the estrogen threshold hypothesis (Barbieri). 1992;166:740-5
Introduction to steroids in the menopause (Samsioe). 1992;166:1980-5
Norgestimate: a clinical overview of a new progestin (Bringer). 1992;166:1969-77
Prolonged effects of a novel, low-dosage continuous progestin–cyclic estrogen replacement program in postmenopausal women (Plunkett and Wolfe). 1992;166:117-21
The role of progestins in hormone replacement therapy (Lobo). 1992;166:1997-2004
Progesterone
The blood pressure response to infusions of angiotensin II during normal pregnancy: relation to plasma angiotensin II concentration, serum progesterone level, and mean platelet volume (Ito et al). 1992;166:1249-53
Gonadotropin and ovarian hormone dynamics in luteal phase defects (Alexander et al). 1992;166:652-7
In the rhesus monkey placental retention after fetectomy at 121 to 130 days' gestation outlasts the normal duration of pregnancy (Nathanielsz et al). 1992;166:1529-35
Laboratory and clinical comparison of a rapid versus a classic progesterone radioimmunoassay for use in determining abnormal and ectopic pregnancies (Peterson et al). 1992;166:562-6
Natural killer cell activity from pregnant subjects is modulated by RU 486 (Hansen et al). 1992;166:87-90
Receiver-operator characteristic, efficiency analysis, and predictive value of serum progesterone concentration as a test for abnormal gestations (Cowan et al). 1992;166:1729-37
Use of urinary luteinizing hormone immunoassays in the assessment of luteal function in infertile women (Corsan et al). 1992;166:41-6
Progestin; *see* **Progestational hormones**
Prostacyclin; *see* **Epoprostenol**
Prostaglandin E2; *see* **Dinoprostone**
Prostaglandins
The effects of glycemia on breathing movements and plasma prostaglandin E concentrations in the sheep fetus (Fowden et al). 1992;166:713-9
The mechanisms of preterm labor: common genital tract pathogens do not metabolize arachidonic acid to prostaglandins or to other eicosanoids (Bennett and Elder). 1992;166:1541-5
Prostaglandin- or endothelium-mediated vasodilation is not involved in the blunted responses of blood vessels to vasoconstrictors in pregnant rats (St-Louis and Sicotte). 1992;166:684-92
Role of prostaglandins in the metabolic responses of the fetus to hypoxia (Hooper et al). 1992;166:1568-75
Protease inhibitors
Direct inhibition of proteases and cervical plasminogen activator by antibiotics (Milwidsky et al). 1992;166:606-12
Protein levels in placenta; *see* **Pregnancy proteins**
Proto-oncogenes
Both 17β-estradiol and tamoxifen induce c-*fos* messenger ribonucleic acid expression in human endometrial carcinoma grown in nude mice (Sakakibara et al). 1992;166:206-12
Puerperium
Postpartum paravaginal hematoma and lower-extremity infection (Chatwani et al). 1992;166:598-600

Pulsatile infusions; *see* **Infusions, intravenous**
Pump, infusion; *see* **Infusion pumps**
Purpura, thrombotic thrombocytopenic
Familial occurrence of thrombotic thrombocytopenic purpura in two sisters during pregnancy (Wiznitzer et al). 1992;166:20-1
Pyridoxine
Successive pregnancies complicated by idiopathic sideroblastic anemia (Barton et al). 1992;166:576-7

Q

Quality of life
Nafarelin in the management of endometriosis: quality of life assessment (Burry). 1992;166:735-9
Questionnaires
Attitudes toward reproduction in a nonpatient population (Wikman et al). 1992;166:121-6

R

Racial factors
Hospitalization for pregnancy complications, United States, 1986 and 1987 (Franks et al). 1992;166:1339-44
Radiation
Early menopause in long-term survivors of cancer during adolescence (Byrne et al). 1992;166:788-93
Radioimmunoassay
Immunoreactive circulating endothelin-1 in normal and hypertensive pregnancies (Schiff et al). 1992;166:624-8
Laboratory and clinical comparison of a rapid versus a classic progesterone radioimmunoassay for use in determining abnormal and ectopic pregnancies (Peterson et al). 1992;166:562-6
Rape
Colposcopy to establish physical findings in rape victims (Slaughter and Brown). 1992;166:83-6
Receiver-operator characteristic; *see* **ROC curve**
Receptors, angiotensin
Changes in human platelet angiotensin II binding sites associated with early pregnancy (Baker et al). 1992;166:255-6
Receptors, epidermal growth factor-urogastrone
Epidermal growth factor receptor expression in cervical intraepithelial neoplasia (Mittal). 1992;166:1593 (Letter)
Receptors, estrogen
Functional analysis of a mutant estrogen receptor isolated from T47Dco breast cancer cells (Leslie et al). 1992;166:1053-61
Receptors, steroid
Steroids receptors in the endometrium during clomiphene citrate treatment (Shabib and Pittrof) (Letter); (Fritz) (Reply). 1992;166:1866-7
Receptors, transferrin
Magnetic cell sorting and the transferrin receptor as potential means of prenatal diagnosis from maternal blood (Gänshirt-Ahlert et al). 1992;166:1350-5
Recurrent spontaneous abortion; *see* **Abortion, habitual**
Regional blood flow
Low-dose infusion of atrial natriuretic peptide in the conscious guinea pig increases blood flow to the placenta of growth-retarded fetuses (Jansson). 1992;166:213-8
Registries
Percutaneous umbilical blood sampling: results from a multicenter collaborative registry (Hickok et al). 1992;166:1614-8
Regression analysis
Composite assessment of gestational age: a comparison of institutionally derived and published regression equations (Hill et al). 1992;166:551-5
Relaxation
Intravenous nitroglycerin for uterine relaxation of an inverted uterus (Altabef et al). 1992;166:1237-8
Religion
Abortion or motherhood, suicide and madness (Ryan). 1992;166:1029-36
Remission, spontaneous
Transient severe unilateral and subsequent bilateral primary fetal hydrothorax with spontaneous resolution at 34 weeks' gestation associated with normal neonatal outcome (Sherer et al). 1992;166:169-70
Renal circulation
Renal autoregulation in midterm and late-pregnant rats (Reckelhoff et al). 1992;166:1546-50
Renal impairment; *see* **Kidney diseases**
Renin-angiotensin system
Changes in human platelet angiotensin II binding sites associated with early pregnancy (Baker et al). 1992;166:255-6
Reproduction
Attitudes toward reproduction in a nonpatient population (Wikman et al). 1992;166:121-6
Contraceptive prevalence, reproductive health, and international morality (Diczfalusy). 1992;166:1037-43
Research
The issue of animal rights and human rights (Heller). 1992;166:1588-9 (Letter)
Residency; *see* **Internship and residency**
Respiratory distress syndrome
Neonatal morbidity according to gestational age and birth weight from five tertiary care centers in the United States, 1983 through 1986 (Robertson et al). 1992;166:1629-45
Prediction of respiratory distress syndrome by a new colorimetric assay (Almog et al). 1992;166:1827-34
A randomized, placebo-controlled trial of betamethasone for the prevention of respiratory distress syndrome at 24 to 28 weeks' gestation (Garite et al). 1992;166:646-51
Retropubic cystourethropexy; *see* **Cystourethropexy**
RH-HR blood-group system
Chorionic villus sampling for fetal Rh typing: clinical implications (Kickler et al). 1992;166:1407-11
Derivation of new mathematic formulas for determining whether a D-positive father is heterozygous or homozygous for the D antigen (Kanter). 1992;166:61-3
Rh isoimmunization
Derivation of new mathematic formulas for determining whether a D-positive father is heterozygous or homozygous for the D antigen (Kanter). 1992;166:61-3
Percutaneous umbilical blood sampling: results from a multicenter collaborative registry (Hickok et al). 1992;166:1614-8
Ribonucleic acid, messenger; *see* **RNA, messenger**
RNA, messenger
Both 17β-estradiol and tamoxifen induce c-*fos* messenger ribonucleic acid expression in human endometrial carcinoma grown in nude mice (Sakakibara et al). 1992;166:206-12
Transforming growth factor-α and epidermal growth factor messenger ribonucleic acid and protein levels in human placentas from early, mid, and late gestation (Bissonnette et al). 1992;166:192-9

ROC curve
Receiver-operator characteristic, efficiency analysis, and predictive value of serum progesterone concentration as a test for abnormal gestations (Cowan et al). 1992; 166:1729-37
Roster
Roster. 1992;166:270-1
RU-486; *see* **Mifepristone**

S

Sacroiliac joint
An integrated therapy for peripartum pelvic instability: a study of the biomechanical effects of pelvic belts (Vleeming et al). 1992;166:1243-7
Sacrospinous ligament; *see* **Ligaments**
Salpingitis
Pelvic inflammatory disease: trends in hospitalizations and office visits, 1979 through 1988 (Rolfs et al). 1992; 166:983-90
Schools, medical
Leadership qualities of obstetrics and gynecology department chairmen of United States medical schools (Bates and Blackhurst). 1992;166:1102-16
Screening; *see* **Mass screening**
Scrotum
Prenatal ultrasonographic diagnosis of fetal scrotal inguinal hernia (Meizner et al). 1992;166:907-9
Second-look laparotomy; *see* **Laparotomy**
Second trimester of pregnancy; *see* **Pregnancy trimester, second**
Seizures
Anticonvulsant effects of magnesium sulfate on hippocampal seizures: therapeutic implications in preeclampsia-eclampsia (Cotton et al). 1992;166:1127-36
Selection bias
Selection bias in in vitro fertilization programs (Hershlag et al). 1992;166:1-3 (Clin. opinion)
Semen preservation
Therapeutic donor insemination: a prospective randomized trial of fresh versus frozen sperm (Subak et al). 1992;166:1597-606
Sensitization
Enhanced sensitization after cordocentesis (Weiner) (Letter); (MacGregor et al) (Reply). 1992;166:1309-10
Septicemia
The effect of fetal sepsis on umbilical cord gases (Meyer et al). 1992;166:612-7
Sex determination
Analysis of peripheral blood of pregnant women for the presence of fetal Y chromosome–specific ZFY gene deoxyribonucleic acid sequences (Kao et al). 1992;166: 1013-9
Sex selection and early pregnancy fetal sex determination: ethics and personal freedom of choice (Stephens) (Letter); (Evans and Fletcher) (Reply). 1992;166:1024-5
Sex preselection
Sex selection and early pregnancy fetal sex determination: ethics and personal freedom of choice (Stephens) (Letter); (Evans and Fletcher) (Reply). 1992;166:1024-5
Sex steroids; *see* **Steroids**
Short umbilical cord; *see* **Umbilical cord, abnormalities**
Shoulder
Brachial plexus palsy: an old problem revisited (Jennett et al). 1992;166:1673-7
Skin patches; *see* **Administration, cutaneous**
Small-for-gestational-age infant; *see* **Infant, small for gestational age**
Smoking
The effect of benzo(a)pyrene on murine ovarian and corpora lutea volumes (Miller et al). 1992;166:1535-41
A reevaluation of estrogen status in postmenopausal women who smoke (Cassidenti et al). 1992;166:1444-8
Training obstetric and family practice residents to give smoking cessation advice during prenatal care (Secker-Walker et al). 1992;166:1356-63
Smooth muscle; *see* **Muscle, smooth**
Society of Perinatal Obstetricians
12th annual meeting of the Society of Perinatal Obstetricians. 1992;166:273-478
Spectroscopy; *see* **Spectrum analysis**
Spectrum analysis
Changes in human fetal cerebral hemoglobin concentration and oxygenation during labor measured by near-infrared spectroscopy (Peebles et al). 1992;166:1369-73
Spermatozoa
Criteria for the diagnosis of infertility (Kessopoulou et al) (Letter); (Aitken) (Reply). 1992;166:264-5
Therapeutic donor insemination: a prospective randomized trial of fresh versus frozen sperm (Subak et al). 1992;166:1597-606
Spina bifida
The California Maternal Serum α-Fetoprotein Screening Program: the role of ultrasonography in the detection of spina bifida (Platt et al). 1992;166:1328-9
Spontaneous abortion; *see* **Abortion**
Spontaneous abortion, recurrent; *see* **Abortion, habitual**
Spontaneous remission; *see* **Remission, spontaneous**
Sports
Vaginal injury resulting from sliding down a water chute (Niv et al). 1992;166:930-1
Stage IB carcinoma; *see* **Carcinoma**
Stains and staining
Characteristics of three vaginal flora patterns assessed by Gram stain among pregnant women (Hillier et al). 1992;166:938-44
Stapling device; *see* **Surgical staplers**
Sterilization, tubal
Tubal sterilization and risk of subsequent hospital admission for menstrual disorders (Shy et al). 1992;166:1698-706
Sternum
Prenatal ultrasonographic findings associated with wide clefting of the upper two thirds of the fetal sternum (Mahone et al). 1992;166:1219-21
Steroid receptors; *see* **Receptors, steroid**
Steroid replacement therapy; *see* **Estrogen replacement therapy**
Steroids
The benefits and risks of hormone replacement therapy: an epidemiologic overview (Harlap). 1992;166:1986-92
Clinical and metabolic considerations of long-term oral contraceptive use (Godsland et al). 1992;166:1955-63
The effect of sex steroids on the skeleton in premenopausal women (Lindsay). 1992;166:1993-6
The efficacy and tolerability of norgestimate/ethinyl estradiol (250 μg of norgestimate/35 μg of ethinyl estradiol): results of an open, multicenter study of 59,701 women (Runnebaum et al). 1992;166:1963-8
Introduction to steroids in the menopause (Samsioe). 1992;166:1980-5

Steroids—cont'd
Norgestimate: a clinical overview of a new progestin (Bringer). 1992;166:1969-77
The role of progestins in hormone replacement therapy (Lobo). 1992;166:1997-2004
The safety of oral contraceptives: epidemiologic insights from the first 30 years (Grimes). 1992;166:1950-4
Steroids from menarche to menopause: introduction (Mishell). 1992;166:1949
Streptococcus agalactiae
Preterm premature rupture of membranes: results of expectant management in patients with cervical cultures positive for group B streptococcus or *Neisseria gonorrhoeae* (Maxwell and Watson). 1992;166:945-9
Stress
Elevated plasma Met-enkephalin levels in the human newborn are a poor indicator of perinatal stress (Martinez et al). 1992;166:1429-35
Stromal enzyme; *see* **Enzymes**
Subcutaneous pump; *see* **Infusion pumps**
Subendocardial ischemia; *see* **Ischemia**
Substance abuse
Drug use or inadequate prenatal care? Adverse pregnancy outcome in an urban setting (Broekhuizen et al). 1992;166:1747-56
Routine urine drug screening at the first prenatal visit (Colmorgen et al). 1992;166:588-90
Substance P
Substance P in peritoneal fluid (Sanfilippo et al). 1992; 166:155-9
Surface-active agents
Effects of antenatal thyrotropin-releasing hormone, antenatal corticosteroids, and postnatal ventilation on surfactant mobilization in premature rabbits (Seidner et al). 1992;166:1551-9
Surgery, operative
The cavitational ultrasonic surgical aspirator for cytoreduction in advanced ovarian cancer (Rose). 1992;166: 843-6
Meta-analysis of surgery in advanced ovarian carcinoma: Is maximum cytoreductive surgery an independent determinant of prognosis? (Hunter et al). 1992;166: 504-11
Surgical staplers
Benefits of cesarean section stapling device understated? (Martens). 1992;166:266-7 (Letter)
The uterine stapling device for cesarean section: a positive view (Pelosi and Pelosi) (Letter); (Villeneuve et al) (Reply). 1992;166:267-8
Survival
Advanced epithelial ovarian carcinoma: long-term survival experience at the community hospital (Unzelman). 1992;166:1663-72

T

T wave; *see* **Electrocardiography**
Tachycardia, supraventricular
Treatment of fetal supraventricular tachycardia with flecainide acetate after digoxin failure (Mills) (Letter); (Kofinas) (Reply). 1992;166:1863
Tamoxifen
Both 17β-estradiol and tamoxifen induce c-*fos* messenger ribonucleic acid expression in human endometrial carcinoma grown in nude mice (Sakakibara et al). 1992; 166:206-12
Rapid growth of leiomyoma in patient receiving tamoxifen (Dilts et al). 1992;166:167-8
Teaching
Leadership qualities of obstetrics and gynecology department chairmen of United States medical schools (Bates and Blackhurst). 1992;166:1102-16
Technology
Frontiers of operative laparoscopy: a review and critique of the evidence (Grimes). 1992;166:1062-71
Infertility and endometriosis: comparison of pregnancy outcomes with laparotomy versus laparoscopic techniques (Gant). 1992;166:1072-81
The need for technology assessment in the reproductive sciences (McDonough). 1992;166:1082-90
Telemetry
First report: telemetry-assisted ambulatory nonstress test (Collins). 1992;166:1020-1 (Letter)
Teratogens
Anticancer drugs during pregnancy: Are we able to discard them? (Kim et al) (Letter); (van der Zee et al) (Reply). 1992;166:265-6
Periconceptional exposure to topical 5-fluorouracil (Otaño et al) (Letter); (Plouffe et al) (Reply). 1992;166:263-4
Terbutaline
Influence of terbutaline on ovine uterine response to prostaglandin E_2 challenge (Reid et al). 1992;166:231-5
Maternal glucose intolerance and the subcutaneous terbutaline pump (Lindenbaum et al). 1992;166:925-8
Three-dimensional ultrasonography; *see* **Ultrasonography**
Thrombocytopenia
Alloimmune thrombocytopenia may be associated with systemic disease (Kay et al). 1992;166:110-1
Fetal polycythemia and thrombocytopenia in pregnancies complicated by maternal diabetes mellitus (Salvesen et al). 1992;166:1287-92
May-Hegglin anomaly: a rare case of maternal thrombocytopenia in pregnancy (Chatwani et al). 1992;166:143-4
The natural history of thrombocytopenia associated with preeclampsia (Catanzarite). 1992;166:770-1 (Letter)
Thrombocytosis
The clinical significance of thrombocytosis in women presenting with a pelvic mass (Chalas et al). 1992;166:974-7
Thrombotic thrombocytopenic purpura; *see* **Purpura, thrombotic thrombocytopenic**
Thromboxanes
Attenuation of the vasoconstrictor effects of thromboxane and endothelin by nitric oxide in the human fetal-placental circulation (Myatt et al). 1992;166:224-30
Endothelium-derived relaxing factor and indomethacin-sensitive contracting factor alter arterial contractile responses to thromboxane during pregnancy (Weiner et al). 1992;166:1171-81
Urinary excretion of prostacyclin and thromboxane metabolites in threatened preterm labor: effect of indomethacin and nylidrin (Kurki et al). 1992;166:150-4
Thyrotropin-releasing hormone
Effects of antenatal thyrotropin-releasing hormone, antenatal corticosteroids, and postnatal ventilation on surfactant mobilization in premature rabbits (Seidner et al). 1992;166:1551-9
Tissue transplantation
Omental graft made simple (Petty). 1992;166:1591 (Letter)
Tocolysis
Influence of terbutaline on ovine uterine response to prostaglandin E_2 challenge (Reid et al). 1992;166:231-5

Maternal glucose intolerance and the subcutaneous terbutaline pump (Lindenbaum et al). 1992;166:925-8
Oral magnesium and the prevention of preterm labor in a high-risk group of patients (Martin et al). 1992;166:144-7
Transient symptomatic subendocardial ischemia during intravenous magnesium sulfate tocolytic therapy (Sherer et al). 1992;166:33-5
Urinary excretion of prostacyclin and thromboxane metabolites in threatened preterm labor: effect of indomethacin and nylidrin (Kurki et al). 1992;166:150-4

Tocolytic therapy; *see* **Tocolysis**

Training; *see* **Education**

Transactions
Transactions of the fifty-eighth annual meeting of the Pacific Coast Obstetrical and Gynecological Society. 1992;166:1595-711
Transactions of the fifty-ninth annual meeting of the Central Association of Obstetricians and Gynecologists. 1992;166:1712-62
Transactions of the tenth annual meeting of the American Gynecological and Obstetrical Society. 1992;166:1029-207

Transcervical embryo transfer; *see* **Embryo transfer**

Transdermal administration; *see* **Administration, cutaneous**

Transferrin receptors; *see* **Receptors, transferrin**

Transforming growth factor alpha
Transforming growth factor-α and epidermal growth factor messenger ribonucleic acid and protein levels in human placentas from early, mid, and late gestation (Bissonnette et al). 1992;166:192-9

Transforming growth factor beta
Regulation of growth of normal ovarian epithelial cells and ovarian cancer cell lines by transforming growth factor-β (Berchuck et al). 1992;166:676-84

Transplacental transmission; *see* **Placenta**

Trichomonas infections
Is trichomoniasis often associated with bacterial vaginosis in pregnant adolescents? (James et al). 1992;166:859-63

Trichomonas vaginalis
Vaginal Po_2 in healthy women and in women infected with *Trichomonas vaginalis*: potential implications for metronidazole therapy (Rashad et al). 1992;166:620-4

Tricuspid valve
Normal fetal Doppler inferior vena cava, transtricuspid, and umbilical artery flow velocity waveforms between 11 and 16 weeks' gestation (Wladimiroff et al). 1992;166:921-4

Triglycerides
Comparison of transdermal and oral estrogen/progestin replacement therapy: effects on serum lipids and lipoproteins (Crook et al). 1992;166:950-5
The Diabetes in Early Pregnancy Study: changes in cholesterol, triglycerides, body weight, and blood pressure (Peterson et al). 1992;166:513-8
Prolonged effects of a novel, low-dosage continuous progestin–cyclic estrogen replacement program in postmenopausal women (Plunkett and Wolfe). 1992;166:117-21

Triplets
Actocardiotocographic monitoring of triplets during vaginal delivery (van Eyck and Arabin). 1992;166:1293-4
Triplet pregnancy involving complete hydatidiform mole and two fetuses: genetic analysis by deoxyribonucleic acid fingerprint (Azuma et al). 1992;166:664-7

Trisomy
Bilateral choroid plexus cysts in trisomy 21 (Rotmensch et al). 1992;166:591-2
Maternal serum α-fetoprotein, β-human chorionic gonadotropin, and unconjugated estriol levels in midtrimester trisomy 18 pregnancies (Greenberg et al). 1992;166:1388-92
Ultrasonographic screening for trisomy 21 (Bernstein) (Letter); (Lockwood et al) (Reply). 1992;166:1591

Trophoblast
Evidence of embryo- and trophoblast-toxic cellular immune response(s) in women with recurrent spontaneous abortion (Hill et al). 1992;166:1044-52

Tubal pregnancy; *see* **Pregnancy, tubal**

Tubal sterilization; *see* **Sterilization, tubal**

Tumor necrosis factor
Stimulation of ovarian tumor cell proliferation with monocyte products, including interleukin-α, interleukin-6, and tumor necrosis factor-α (Wu et al). 1992;166:997-1007
Tumor necrosis factor in preterm and term labor (Romero et al). 1992;166:1576-87

Twin-twin transfusion syndrome; *see* **Fetofetal transfusion**

Twins
Breech extraction of low-birth-weight second twins: Can cesarean section be justified? (Davison et al). 1992;166:497-502
Triplet pregnancy involving complete hydatidiform mole and two fetuses: genetic analysis by deoxyribonucleic acid fingerprint (Azuma et al). 1992;166:664-7
The Zavanelli maneuver applied to locked twins (Swartjes et al). 1992;166:532

U

Ultrasonography
The cavitational ultrasonic surgical aspirator for cytoreduction in advanced ovarian cancer (Rose). 1992;166:843-6
Increasing use of gynecologic ultrasonography (Goldstein) (Letter); (Willson) (Reply). 1992;166:1310-1
Ovarian cancer screening (Gosink) (Letter); (Creasman and DiSaia) (Reply). 1992;166:1591-3
Transvaginal ultrasonographic quantitative assessment of accumulated cul-de-sac fluid (Rosen et al). 1992;166:542-4

Ultrasonography, prenatal; *see also* **Prenatal diagnosis**
The California Maternal Serum α-Fetoprotein Screening Program: the role of ultrasonography in the detection of spina bifida (Platt et al). 1992;166:1328-9
Comment on fetal breathing movements after premature rupture of membranes (Kivikoski and Amon) (Letter); (Roberts) (Reply). 1992;166:770
Comparison of dynamic image and pulsed Doppler ultrasonography for the diagnosis of the small-for-gestational-age fetus (Miller and Gabert). 1992;166:1820-6
Comprehensive fetal assessment with three ultrasonographic characteristics (James et al). 1992;166:1486-95
Diagnosis of cervical change in pregnancy by means of transvaginal ultrasonography (Joffe et al). 1992;166:896-900
Doppler ultrasonographic features of the developing placental circulation: correlation with anatomic findings (Jauniaux et al). 1992;166:585-7
Emergency room use of transvaginal ultrasonography by obstetrics and gynecology residents (Timor-Tritsch et al). 1992;166:866-72

Ultrasonography, prenatal—cont'd
Fetal humeral length to detect Down syndrome (Rotmensch et al). 1992;166:1330-4
The frequency of breech presentation by gestational age at birth: a large population-based study (Hickok et al). 1992;166:851-2
Intracerebral, aortic, and umbilical artery flow velocity waveforms in the late-first-trimester fetus (Wladimiroff et al). 1992;166:46-9
Mechanism of recurrent spontaneous abortion. I. Ultrasonographic findings (Stern and Coulam). 1992;166:1344-52
A model-based prediction for transvaginal ultrasonographic identification of early intrauterine pregnancy (Shapiro et al). 1992;166:1495-500
Normal fetal Doppler inferior vena cava, transtricuspid, and umbilical artery flow velocity waveforms between 11 and 16 weeks' gestation (Wladimiroff et al). 1992;166:921-4
Prenatal ultrasonographic diagnosis of fetal scrotal inguinal hernia (Meizner et al). 1992;166:907-9
Prenatal ultrasonographic findings associated with wide clefting of the upper two thirds of the fetal sternum (Mahone et al). 1992;166:1219-21
The primary application of three-dimensional ultrasonography in obstetrics (Kuo et al) 1992;166:880-6
The tip of the iceberg and the best fit in ultrasonographic dating of pregnancy (Rossavik) (Letter); (Goldstein) (Reply). 1992;166:1867-8
Transabdominal chorionic villus sampling: a modified free-hand ultrasonographically guided technique (Hill and Laifer). 1992;166:512
Ultrasonographic dating of pregnancy causes significant errors in Down syndrome risk assessment that may be minimized by use of biparietal diameter–based means (Reynolds et al). 1992;166:872-7
Ultrasonographic screening for trisomy 21 (Bernstein) (Letter); (Lockwood et al) (Reply) 1992;166:1591
The use of neural network for the ultrasonographic estimation of fetal weight in the macrosomic fetus (Farmer et al). 1992;166:1467-72
Uterine and umbilical flow velocity waveforms in normotensive and hypertensive subjects during the angiotensin II sensitivity test (Erkkola and Pirhonen). 1992;166:910-6
Validity of postnatal assessments of gestational age: a comparison of the method of Ballard et al. and early ultrasonography (Alexander et al). 1992;166:891-5

Umbilical arteries
Applicability of the Poiseuille equation to umbilical artery velocimetry (Degani) (Letter); (Wright and Ridgway) (Reply). 1992;166:766-7
Comprehensive fetal assessment with three ultrasonographic characteristics (James et al). 1992;166:1486-95
Intracerebral, aortic, and umbilical artery flow velocity waveforms in the late-first-trimester fetus (Wladimiroff et al). 1992;166:46-9
Normal fetal Doppler inferior vena cava, transtricuspid, and umbilical artery flow velocity waveforms between 11 and 16 weeks' gestation (Wladimiroff et al). 1992;166:921-4
Umbilical artery flow velocity after vibratory acoustic stimulation (Nakamura et al) (Letter); (Gagnon et al) (Reply). 1992;166:1865-6
Uterine and umbilical flow velocity waveforms in normotensive and hypertensive subjects during the angiotensin II sensitivity test (Erkkola and Pirhonen). 1992;166:910-6

Umbilical cord
Change in electrocardiogram T-wave amplitude during umbilical cord compression is predictive of fetal condition in sheep (Watanabe et al). 1992;166:246-55
The effect of fetal sepsis on umbilical cord gases (Meyer et al). 1992;166:612-7
Enhanced sensitization after cordocentesis (Weiner) (Letter); (MacGregor et al) (Reply). 1992;166:1309-10
The physiologic mechanisms of variable decelerations (Ball and Parer). 1992;166:1683-9

Umbilical cord, abnormalities
The short umbilical cord (Collins). 1992;166:268-9 (Letter)

Ureaplasma
Eradication of *Ureaplasma urealyticum* from the amniotic fluid with transplacental antibiotic treatment (Romero et al). 1992;166:618-20
Ureaplasma urealyticum resistance to erythromycin: confirmed by clinical trial (Kundsin et al) (Letter); (Eschenbach et al) (Reply). 1992;166:1864-5

Uric acid
Plasma endothelin levels in preeclampsia: elevation and correlation with uric acid levels and renal impairment (Clark et al). 1992;166:962-8

Urinary incontinence
Urinary incontinence: correlation of history and brief office evaluation with multichannel urodynamic testing (Summitt et al). 1992;166:1835-44

Urinary incontinence, stress
Modified retropubic cystourethropexy II (Goodno and Powers). 1992;166:1678-82

Urinary tract, pathology
Fetal urine biochemistry in the assessment of obstructive uropathy (Nicolaides et al). 1992;166:932-7

Urine
Fetal urine biochemistry in the assessment of obstructive uropathy (Nicolaides et al). 1992;166:932-7
Routine urine drug screening at the first prenatal visit (Colmorgen et al). 1992;166:588-90
Urinary excretion of prostacyclin and thromboxane metabolites in threatened preterm labor: effect of indomethacin and nylidrin (Kurki et al). 1992;166:150-4

Urodynamics
Urinary incontinence: correlation of history and brief office evaluation with multichannel urodynamic testing (Summitt et al). 1992;166:1835-44

Uropathy; *see* Urinary tract, pathology

Uterine arteries
Endothelium-derived relaxing factor and indomethacin-sensitive contracting factor alter arterial contractile responses to thromboxane during pregnancy (Weiner et al). 1992;166:1171-81
Lack of reactivity of uterine arteries from patients with obstetric hemorrhage (Nelson and Suresh). 1992;166:1436-43

Uterine contraction
Changes in human fetal cerebral hemoglobin concentration and oxygenation during labor measured by near-infrared spectroscopy (Peebles et al). 1992;166:1369-73
The presence of platelet-activating factor binding sites in

human myometrium and their role in uterine contraction (Zhu et al). 1992;166:1222-7

Uterine diseases
Infarction of the uterus from subacute incomplete inversion (Romo et al). 1992;166:878-9

Uterine hemorrhage
Lack of reactivity of uterine arteries from patients with obstetric hemorrhage (Nelson and Suresh). 1992;166:1436-43

Uterine neoplasms
Accuracy of frozen-section diagnosis at surgery in clinical state I and II endometrial carcinoma (Shim et al). 1992;166:1335-8
The benefits and risks of hormone replacement therapy: an epidemiologic overview (Harlap). 1992;166:1986-92
Both 17β-estradiol and tamoxifen induce c-*fos* messenger ribonucleic acid expression in human endometrial carcinoma grown in nude mice (Sakakibara et al). 1992;166:206-12
Deoxyribonucleic acid analysis by flow cytometry of uterine leiomyosarcomas and smooth muscle tumors of uncertain malignant potential (Peters et al). 1992;166:1646-54
Immunohistochemical detection of the multi-drug-resistance marker P-glycoprotein in uterine cervical carcinomas and normal cervical tissue (Schneider et al). 1992;166:825-9
Insulin-like growth factor I and II binding in human myometrium and leiomyomas (Chandrasekhar et al). 1992;166:64-9
Phase II trial of ifosfamide and mesna in leiomyosarcoma of the uterus: a gynecologic oncology group study (Sutton et al). 1992;166:556-9
Rapid growth of leiomyoma in patient receiving tamoxifen (Dilts et al). 1992;166:167-8
Treatment of uterine fibroids: current findings with gonadotropin-releasing hormone agonists (Adamson). 1992;166:746-51

Uterine prolapse
Anatomic aspects of vaginal eversion after hysterectomy (DeLancey). 1992;166:1717-28

Uteroplacental blood flow; *see* **Fetal blood**

Uterus
Influence of labor and oxytocin on in vitro leukotriene release by human fetal membranes and uterine decidua at term gestation (Pasetto et al). 1992;166:1500-6
Intravenous nitroglycerin for uterine relaxation of an inverted uterus (Altabef et al). 1992;166:1237-8

Uterus, blood supply
Interrelationship and clinical significance of increased resistance in the uterine arteries in patients with hypertension or preeclampsia or both (Kofinas et al). 1992;166:601-6
Uterine and umbilical flow velocity waveforms in normotensive and hypertensive subjects during the angiotensin II sensitivity test (Erkkola and Pirhonen). 1992;166:910-6
Venous drainage of the human uterus: respiratory gas studies in normal and fetal growth-retarded pregnancies (Pardi et al). 1992;166:699-706

Uterus, drug effects
Influence of terbutaline on ovine uterine response to prostaglandin E_2 challenge (Reid et al). 1992;166:231-5

Uterus, injuries
Nonsurgical management of penetrating uterine trauma in pregnancy: a case report (Grubb). 1992;166:583-4

V

Vagina
Anatomic aspects of vaginal eversion after hysterectomy (DeLancey). 1992;166:1717-28
Human vaginal leukocytes and the effects of vaginal fluid on lymphocyte and macrophage defense functions (Hill and Anderson). 1992;166:720-6

Vagina, injuries
Vaginal injury resulting from sliding down a water chute (Niv et al). 1992;166:930-1

Vagina, surgery
Upper vaginectomy for in situ and occult, superficially invasive carcinoma of the vagina (Hoffman et al). 1992;166:30-3

Vaginal birth after cesarean
Vaginal birth after cesarean delivery: Are there useful and valid predictors of success or failure? (Pickhardt et al). 1992;166:1811-9

Vaginal delivery; *see* **Delivery**

Vaginal neoplasms
Upper vaginectomy for in situ and occult, superficially invasive carcinoma of the vagina (Hoffman et al). 1992;166:30-3

Vaginal pessary; *see* **Pessaries**

Vaginal radical hysterectomy; *see* **Hysterectomy, vaginal**

Vaginal smears
Cervical cytology: a randomized comparison of four sampling methods (McCord et al). 1992;166:1772-9
Papanicolaou smear abnormalities in ambulatory care sites for women infected with the human immunodeficiency virus (Marte et al). 1992;166:1232-7

Vaginectomy; *see* **Vagina, surgery**

Vaginitis
Characteristics of three vaginal flora patterns assessed by Gram stain among pregnant women (Hillier et al). 1992;166:938-44
Incidence of pelvic inflammatory disease after first-trimester legal abortion in women with bacterial vaginosis after treatment with metronidazole: a double-blind, randomized study (Larsson et al). 1992;166:100-3
Is trichomoniasis often associated with bacterial vaginosis in pregnant adolescents? (James et al). 1992;166:859-63

Vascular resistance
Interrelationship and clinical significance of increased resistance in the uterine arteries in patients with hypertension or preeclampsia or both (Kofinas et al). 1992;166:601-6

Vascular smooth muscle; *see* **Muscle, smooth, vascular**

Vasoconstriction
Attenuation of the vasoconstrictor effects of thromboxane and endothelin by nitric oxide in the human fetal-placental circulation (Myatt et al). 1992;166:224-30
Nω-Nitro-L-arginine, and inhibitor of nitric oxide synthesis, increases blood pressure in rats and reverses the pregnancy-induced refractoriness to vasopressor agents (Molnár and Hertelendy). 1992;166:1560-7
Prostaglandin- or endothelium-mediated vasodilation is not involved in the blunted responses of blood vessels to vasoconstrictors in pregnant rats (St-Louis and Sicotte). 1992;166:684-92

Vasodilation
Prostaglandin- or endothelium-mediated vasodilation is not involved in the blunted responses of blood vessels to vasoconstrictors in pregnant rats (St-Louis and Sicotte). 1992;166:684-92

Vena cava, inferior
Inferior vena cava flow velocity waveforms in appropriate- and small-for-gestational-age fetuses (Rizzo et al). 1992; 166:1271-80
Normal fetal Doppler inferior vena cava, transtricuspid, and umbilical artery flow velocity waveforms between 11 and 16 weeks' gestation (Wladimiroff et al). 1992;166:921-4

Ventilation
Effects of antenatal thyrotropin-releasing hormone, antenatal corticosteroids, and postnatal ventilation on surfactant mobilization in premature rabbits (Seidner et al). 1992;166:1551-9

von Willebrand factor
Preeclampsia, von Willebrand factor antigen, and endothelial cells (Blann) (Letter); (Taylor et al) (Reply). 1992; 166:769-70

Vulvar diseases
Necrotizing fasciitis of the vulva (Stephenson et al). 1992;166:1324-7
Superficial laser vulvectomy. V. Surgical debulking is enhanced by adjuvant systemic interferon (Reid et al). 1992;166:815-20

Vulvar neoplasms
In situ and invasive vulvar cancer incidence trends (1973 to 1987) (Sturgeon et al). 1992;166:1482-5

Vulvovaginal moniliasis; *see* **Moniliasis, vulvovaginal**

W

Water chute
Vaginal injury resulting from sliding down a water chute (Niv et al). 1992;166:930-1

WISH cells; *see* **Amnion**

Wounds and injuries
Acute genital injury in the prepubertal girl (Pokorny et al). 1992;166:1461-6
Nonsurgical management of penetrating uterine trauma in pregnancy: a case report (Grubb). 1992;166: 583-4

Y

Y chromosome
Analysis of peripheral blood of pregnant women for the presence of fetal Y chromosome–specific ZFY gene deoxyribonucleic acid sequences (Kao et al). 1992;166: 1013-9

Z

Zavanelli maneuver
The Zavanelli maneuver applied to locked twins (Swartjes et al). 1992;166:532

ZFY gene
Analysis of peripheral blood of pregnant women for the presence of fetal Y chromosome–specific ZFY gene deoxyribonucleic acid sequences (Kao et al). 1992;166: 1013-9

OBSTETRICIAN/GYNECOLOGIST
KANSAS CITY METROPOLITAN AREA

Exceptional opportunity exists for a BC/BE OB/GYN in a large, expanding and independent multi-specialty group with an excellent referral base. Practice is conveniently located close to hospitals, affordable luxury housing and nationally recognized school systems in stable neighborhoods. A very attractive and flexible incentive package is available. Please send Curriculum Vitae to:

JOHN STORM

FAX (913) 281-8494

HARVARD MEDICAL SCHOOL
DEPARTMENT OF CONTINUING EDUCATION

THE MOLECULAR BIOLOGY OF WOMEN'S HEALTH
Breast and Reproductive Tract

September 21-23, 1992
Ritz-Carlton Hotel, Boston

Course Directors
Christopher P. Crum, M.D.
George L. Mutter, M.D.

GUEST FACULTY
Andrew Berchuck, Duke University
Lutz Gissman, German Cancer Research Center
Gerard Nuovo, State University of New York
David Page, The Whitehead Institute
Dennis Slamon, UCLA

This course, sponsored by the Division of Women's and Perinatal Pathology at Brigham and Women's Hospital, will critically review recent advances in molecular biology relevant to gynecologic, obstetric, and breast pathology.

For further information, contact
Harvard MED-CME, P.O. Box 825, Boston, MA 02115

RESIDENCY EDUCATION COORDINATOR FOR OB/GYN

Bridgeport Hospital is a 660-bed non-profit community hospital and teaching facility located in picturesque Fairfield County and affiliated with the Yale School of Medicine. It is accredited by JCAHO and the State of Connecticut and is a member of the American Hospital Association. The hospital is conveniently located to New Haven, New York City, and Boston, offering a wide range of recreational and cultural opportunities.

We are seeking a Residency Education Coordinator for OB/GYN to be responsible for coordinating the educational programs for residents in OB/GYN. Additionally, you will develop formal programs of education in Urogynecology, benign breast disease, and GYN surgical techniques; coordinate the 24-hour in-house coverage for the residency program, and provide coverage of resident clinical activity during weekdays.

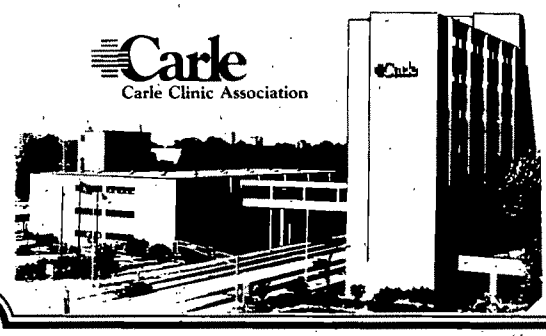
Board Certification in Obstetrics and Gynecology and a minimum 5 years' experience and demonstrated competence in resident education and educational programs are essential. Experience/interest in Urogynecology.

Interested applicants are encouraged to send their resume to: Mr. Robert VanHeiningen, Assistant Vice President for Human Resources, Bridgeport Hospital, 267 Grant Street, P.O. Box 5C00, Dept. AJ/OB/GYN, Bridgeport, CT 06610.

BRIDGEPORT HOSPITAL

A century ago, we made a commitment.
We've kept it.

An equal opportunity employer.



DIRECTOR
OBSTETRICS AND GYNECOLOGY
Broadlawns Medical Center
Des Moines, Iowa

The University of Iowa and Broadlawns Medical Center, a 200+ bed county supported public teaching hospital, are seeking a Director for the Department of OB/GYN. Activities will include supervising patient care as well as teaching of Family Practice residents, a rotating OB/GYN Resident, and medical students in our OB service (500 births per year and growing). Department includes medical office clinic facilities, a new Family Birthing Center, a Family Planning Program and a newly created mid-wife position. Basic requirements include an M.D. or D.O. degree, and Board Certification or active candidacy of the American Board of Obstetrics and Gynecology, extensive practice experience, and the ability to direct staff and programs to support the service and educational goals of the institution. Clinical teaching experience would be desirable. A university medical school faculty appointment is possible for appropriate candidates. If interested, contact D.J. Walter, MD, Director of Medical Education, Broadlawns Medical Center, 18th & Hickman Road, Des Moines, Iowa, (515) 282-2203. Minorities and women especially encouraged to apply. The University and Broadlawns are Equal Opportunity/Affirmative Action Employers.

OBSTETRICIANS AND GYNECOLOGISTS
Illinois

OB/GYN Physicians needed to join Carle Clinic Association, a 225 physician, multi-specialty group practice in central Illinois with opportunities at the main campus as well as three additional sites - Urbana, Bloomington, Danville and Mattoon/Charleston. These communities offer recreational, cultural and educational amenities. Benefit package includes a competitive salary with partnership and income sharing plan after two years, professional liability insurance, health, life and disability insurance and generous vacation and meeting time. Contact:

Robert C. Parker, Jr., MD
Medical Director
Carle Clinic Association
602 W. University, Urbana, Illinois 61801
Phone 217-383-3399 - Fax 217-383-3163

Perinatologist Needed in Coastal New Jersey

2 member group is seeking a third perinatologist (BE/BC). We are active practitioners of perinatology and we also serve as integral members of the teaching team for a residency in Obstetrics and Gynecology.

We engage in both in-patient and out-patient activities, and all skills related to maternal fetal medicine may be used within our practice. Strong ultrasound skills are required, and the current practice consists of antenatal diagnosis, genetic counseling, amniocentesis, CVS and PUBS. We will insist on comfort and competence in basic obstetrical practice.

We are located about 1.5 hours from both New York City and Philadelphia, and the area provides a suburban life style.

Contact: Glenn Herman, M.D.
David Wallace, M.D.
Telephone: (908) 870-3600
Fax: (908) 870-0119

Obstetrician/Gynecologist

Guaranteed Income
No Start-Up Costs

The United States Military Academy at West Point, New York is offering an excellent opportunity for a BC OB/GYN. Set in the Hudson River Valley, West Point is far enough from New York City to offer small town living with easy access to surrounding winter and summer recreation while being close enough to New York City to take advantage of all the cultural opportunities.

West Point has a 65-bed hospital with a Level I Nursery, a healthy patient population, and approximately 300 deliveries per year.

PERINATOLOGIST OGDEN, UTAH

An outstanding opportunity exists for a perinatologist to set up a consultative practice in Ogden, Utah. The physician will be an employee of McKay-Dee Hospital, a 415-bed community facility. Office space, personnel and equipment will be provided by the hospital. The successful candidate will be an integral part of Intermountain Health Care's Perinatal Group.

Ogden, Utah is a beautiful community of 69,000, with a service population of 260,000. There is an abundance of outdoor recreation available, including skiing, snowmobiling, hunting, fishing, boating, swimming and camping. A variety of cultural events entertain and amuse Ogden residents, such as the symphony, the ballet, museums, art galleries and festivals. Ogden is a short 40 minutes from Salt Lake City where more professional sports and cultural events may be found.

For more information, send a CV to:

PERINATAL ASSOCIATES OF NORTHERN CALIFORNIA

Are you a clinical perinatologist? There is still time to join 4 perinatologists and one medical geneticist looking for one more perinatologist who: desires superior environment for patient care, in a private, modern level 3 facility doing 6,000 deliveries a year with superior perinatal outcome; likes personal, direct hands-on patient care; needs PUBS, IUTxF, CVS and complicated pregnancies, level 2 ultrasound; demands partners, not superiors; wants to live in clean, warm, not humid, snow-free (but 60 minutes from skiing) Sacramento, California; feels one's family has prior ties; and is committed to the private practice of medicine. For more information, call (916) 733-1755.

PERINATOLOGIST
Denver, Colorado

Rose Medical Center, Denver, Colorado is seeking a **second** BE/BC perinatologist to work full-time in a 400-bed private community hospital adjacent to the University of Colorado Health Sciences Center. With 3,500 deliveries per year, and 27 University Residents rotating through the department annually, Rose is the major private teaching affiliate of the University.

Responsibilities include, primary patient care, private consultation, physician, resident, and nursing education, clinical research, and a limited private practice in perinatology. This individual can expect frequent interaction with the Maternal/Fetal Division at the University of Colorado, and will be eligible for an appropriate clinical appointment at the University. All clinical responsibilities will be shared with the current full-time perinatologist at Rose. Additional call coverage is provided by other perinatologists in the Denver metro area.

A competitive salary guarantee is being offered, with excellent fringe benefits including malpractice insurance.

Qualified applicants, including individuals completing fellowship in June, 1993, should forward CV's to:

Robert E. Wall, M.D., Chairman
Department of Obstetrics & Gynecology
Rose Medical Center
4500 East Ninth Avenue, Suite 220-South
Denver, Colorado 80220
Telephone: (303) 320-2077

Primary Care Our Primary Concern

With a commitment to excellence and a focus on the total needs of each patient, Riverside Medical Center blends a 'primary' approach with major centers of excellence in cardiology, chemical dependency, mental health, neuro-sensory, obstetrics and orthopedics.

Picture yourself as a physican partner in the Minneapolis/St. Paul area's most comprehensive, integrated, primary care-based system of health care.

Positions available for board-certified and board-eligible Obstetrician/Gynecologists.

Riverside Medical Center...
where primary care is our primary concern.

THE DEPARTMENT OF OBSTETRICS AND GYNECOLOGY UNIVERSITY OF WISCONSIN MEDICAL SCHOOL

is seeking applicants for two (2) full-time faculty positions for a new women's health center and academic program at its Milwaukee Clinical Campus.

Sinai Samaritan Medical Center has recently consolidated its obstetrical and gynecological services in a redesigned facility in downtown Milwaukee. The department supports a residency program, the largest perinatal service in Wisconsin (5500 deliveries), consultative ultrasound, genetic and infectious disease programs, and reproductive/endocrine services (including an IVF program). The department is affiliated with Planned Parenthood of Wisconsin and St. Luke's Medical Center in Milwaukee.

Qualifications include a board candidacy or certification in obstetrics and gynecology and a commitment to teaching residents, medical students, and clinical research. Qualifications for the two positions for GENERAL OB/GYN can take into consideration special individual interests. Special expertise of interest for the department are:

- —STATEWIDE FAMILY PLANNING
  (Part-time medical director, Planned Parenthood)
- —OPERATIVE LAPAROSCOPY, HYSTEROSCOPY
- —UROGYNECOLOGY
- —OB/GYN ULTRASOUND

Private practice opportunities are also available in an associated offsite multispecialty clinic and all faculty members participate in a group practice at the institution. Contact:

OB/GYN Generalist Assistant Professor

A full-time position is available in the Department of Obstetrics and Gynecology, University of Kentucky, Lexington. Applicants should be board eligible or board certified in obstetrics and gynecology. Special interest in resident and student education, uro-gynecology, adolescent Ob/Gyn or sexual dysfunction is desired.

Responsibilities of this position include inpatient and outpatient clinical practice activities; medical education of residents, interns, and medical students. Clinical and/or basic science investigation opportunities are available. This is a unique opportunity for a patient oriented physician. Applicants should send curriculum vitae to:

Frank C. Miller, M.D.
Professor and Chairman
Department of Obstetrics and Gynecology
University of Kentucky Medical Center
800 Rose Street, MN 318
Lexington, KY 40536-0084

THE UNIVERSITY OF KENTUCKY IS AN AFFIRMATIVE ACTION, EQUAL OPPORTUNITY EMPLOYER AND ACTIVELY SEEKS THE CANDIDACY OF MINORITIES AND WOMEN.

MATERNAL-FETAL MEDICINE

The University of Louisville Department of OB/GYN is actively recruiting faculty (rank open) to its MFM Division. An attractive balance of teaching, research and clinical activity with a very competitive income is offered. The U of L is an Equal Employment Opportunity institution. Interested individuals should send curriculum vitae to me or contact me at (502) 588-1913.

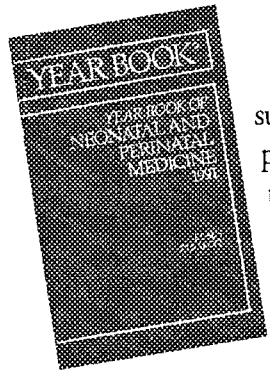
J. A. Spinnato, M.D.
Director, Division of Maternal-Fetal Medicine
Dept. of OB/GYN,
University of Louisville
Louisville, KY 40292

Chief, Department of OB/GYN— Sinai Hospital of Baltimore, a 463-bed hospital with major teaching affiliations with the Johns Hopkins University School of Medicine, is seeking a Chief of OB/GYN. Candidates should be board certified (sub-specialty certification is desirable) and have an outstanding academic record which would merit an appointment at the Associate Professor/Professor level at Johns Hopkins. The OB/GYN department at Sinai has strong teaching, research and clinical programs. As a comprehensive womens' services program, with in excess of 4000 births annually, and a regional maternal neonatal transfer site, the department includes programs in infertiity, including a new IVF laboratory, climacteric gynecology, urogynecology and an off site womens' health center. Interested applicants should send their CV to the Chairperson of the Search Committee: Bart Chernow, M.D., Professor of Medicine and Physician-in-Chief, Sinai Hospital, 2401 W. Belvedere Ave., Baltimore, MD 21215. Sinai Hospital is an Equal Opportunity Employer.

UNIVERSITY OF MICHIGAN MEDICAL CENTER

The Department of Obstetrics and Gynecology at the University of Michigan Medical Center is seeking two board certified or eligible obstetricians/gynecologists to serve as clinical track faculty members providing primarily obstetrical patient care. Salary and rank will be commensurate with the candidates' training and experience. Please direct inquiries and curriculum vitae to:

Rudi Ansbacher, M.D., M.S.
Professor and Interim Chair
Department of Obstetrics and Gynecology
The University of Michigan Medical Center
Medical Professional Building D2202/0718
1500 E. Medical Center Drive
Ann Arbor, MI 48109-0718



The University of Michigan is an affirmative action/equal opportunity employer. Codes 30 and 56.

UCLA INTERCAMPUS MEDICAL GENETICS TRAINING PROGRAM

The UCLA intercampus post-doctoral research training program in Medical Genetics utilizes the research and clinical resources of its affiliated campuses and teaching hospitals. The program is open to academically oriented applicants with the M.D., Ph.D., D.D.S. or equivalent degrees. A wide variety of research training opportunities in molecular, biochemical, immuno-, cancer, cyto-, somatic cell, population and clinical genetics are available. The program also meets all the requirements of the American Board of Medical Genetics. Clinical genetics fellowships are available at each of the affiliated hospitals. Application forms are available from David Rimoin, M.D., Ph.D., Department of Pediatrics, Cedars-Sinai Medical Center, 8700 Beverly Blvd., Los Angeles, CA 90048.

A surprisingly uncomplicated, time-saving way to stay up-to-date with what's happening in neonatal and perinatal medicine around the world . . .

The year's most significant journal articles in neonatal and perinatal medicine – selected, abstracted, analyzed, and bound together in one easy-to-use reference!

With your needs and time restrictions in mind, the editors of the **Year Book** survey over 900 medical and scientific journals, searching for the ones that are sure to make a difference in your practice. For the 1991 volume, they've selected and condensed over 200 articles that cover the latest advances in neonatal and perinatal medicine – developments you need to know about.

This collection of articles in itself would be a valuable addition to your library, but the **Year Book** service goes one step beyond mere information: you also get thought-provoking commentaries that assess each article's significance and its clinical implications, while supplying useful background information, and discussing the results of other relevant studies.

The **1991 Year Book of Neonatal and Perinatal Medicine** gives you not only what you need to know, but tells you why you need to know it! Here are just a few of the topics you'll find in the 1991 volume: fetal surgery, amniocentesis and ultrasound revisited, prepregnancy glycemic control and congenital malformations, and much more!

To review this outstanding resource **free** for 30 days, just mail the Free Examination Certificate below or call . . .

Toll-Free 1-800-426-4545

(To speed your order, mention code "MCA-105").

If you aren't completely satisfied with its scope of information and insight, just send it back and owe nothing. It is simply the best, most convenient way to stay on top of the newest developments in your fast-growing field.

FREE EXAMINATION CERTIFICATE

Please send my 30-day FREE examination copy of the **1991 Year Book of Neonatal and Perinatal Medicine** (22117). If I decide to keep the book I'll pay $57.95* plus shipping and handling.

When you purchase a Year Book, we'll also send you an automatic notice of future volumes about two months before they publish. This system was designed for your convenience and to take up as little of your time as possible. If you do not want the Year Book, the advance notice makes it easy for you to let us know. And if you elect to receive the new Year Book, you need do nothing. We will send it on publication. No worry. No wasted motion. And, of course, every Year Book is yours to examine free of charge for 30 days.

"Smart, current, in-depth, tough, unique, charismatic, authoritative, handy, relevant, lucid, thorough, convenient, detailed, pithy, top-notch, helpful, sagacious, indispensable, comprehensive, timely, thought-provoking, incisive, straightforward, lively, astute, invaluable, concise, fact-packed, and one-of-a-kind."

Okay. So maybe we're going a little overboard. But our subscribers are an opinionated and enthusiatic bunch. Nearly one in four physicians practicing today is a Year Book subscriber and they are vocal in their loyalty.

And why not? A subscription to the Year Book gives you all the past year's most essential ob/gyn articles condensed for quick and easy reading, and expert advice to help you put the latest findings and techniques to work immediately.

Let's be honest, though, no list of two-dollar words can really convey a book's usefulness and value. *You've got to evaluate it for yourself.*

That's why we're offering you this no-risk, no-obligation, 30-day free trial of the Year Book. Just call or mail the attached coupon and we'll send you a free examination copy. Put it to work for a month, and if you're not completely satisfied for any reason, just send it back and owe nothing.

But we hope you might want to send us a few adjectives of your own instead–extraordinary, versatile, and revolutionary are still available.

❑ Yes! Please send my 30-day free approval copy of the *1992 Year Book of Obstetrics and Gynecology* (22636) according to the service terms described below. If I decide to keep the book I'll pay just $59.95 (plus shipping, handling, and state sales tax where appropriate).

The Year Book of Obstetrics and Gynecology Service Guarantee

When you subscribe to the Year Book, we'll send you an advance notice of future volumes about two months before they publish. This automatic notice system is designed to take up as little of your time as possible. If you do not want the Year Book, the advance notice makes it it quick and easy for you to let us know your decision; and you will always have at least 20 days to decide. If we don't hear from you, we'll send you the new volume as soon as it's available. And, of course, the Year Book is yours to examine free of charge for 30 days (postage, handling and applicable sales tax are added to each shipment).

Current Obstetric Medicine, Volume 1
Premier Edition

In the Pregnant Patient + Medical Disorder equation, where do you fit in?

A pregnant patient with a medical disorder poses a unique and special challenge. You need to understand her disease and how it affects her pregnancy. You also need to recognize the physiologic signs of a normal gestation in order to best treat her overall condition.

In this premier volume of **Current Obstetric Medicine**, international authorities discuss recent developments in obstetric medicine, summarizing pertinent findings and trends from the literature published within the last two years. They also add their own critical commentary, providing new perspectives on the problems you face. Concentrating on emerging treatments and insights, the authorities focus on how these innovations affect your patients and your practice. This combination of the latest research and expert interpretation makes **Current Obstetric Medicine, Volume 1** a vital clinical reference.

You'll get a multidisciplinary perspective of new diagnostic techniques and therapies, such as preconception counseling and management of asthma, rhinitis, and anaphylaxis during pregnancy. A wide spectrum of conditions and problems are covered, including renal disease, postpartum thyroiditis, diabetes, and accidents. And each issue in **Current Obstetric Medicine** is discussed in terms of its clinical significance—so you can start applying the best available treatments to your patients' care immediately.

*To review this outstanding resource **free for 30 days**, simply mail the Free Examination Certificate below or call **Toll-Free 1-800-426-4545** (To speed your order, mention code "MCA-029"). If you aren't completely satisfied with its scope of information and insight, just send it back and owe nothing. It's an easy way to place yourself in the patient care equation.*

Each peach tablet contains 1 mg norethindrone and 0.035 mg ethinyl estradiol. Each green tablet in 28-day regimen contains inert ingredients.

IMPORTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information provided with the product and therefore should not be used as the basis for prescribing the product. This summary was prepared by deleting from the complete prescribing information certain text, tables and references. The physician should be thoroughly familiar with the complete prescribing information before prescribing the product.

INDICATIONS AND USAGE: PREVENTION OF PREGNANCY.

CONTRAINDICATIONS: Oral contraceptives should not be used in women who currently have the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophlebitis or thromboembolic disorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected carcinoma of the breast. 5. Carcinoma of the endometrium or other known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Cholestatic jaundice of pregnancy or jaundice with prior pill use. 8. Hepatic adenomas or carcinomas. 9. Known or suspected pregnancy.

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia, and gallbladder disease, although the risk of serious morbidity or mortality is very small in healthy women without underlying risk factors. The risk of morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, obesity and diabetes. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks. The information contained in this brief summary is principally based on studies carried out in patients who used oral contraceptives with higher formulations of estrogens and progestogens than those in common use today. The effect of long term use of the oral contraceptives with lower formulations of both estrogens and progestogens remains to be determined. Throughout this brief summary epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of a disease, namely a *ratio* of the incidence of a disease among oral contraceptive users to that among nonusers. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide a measure of attributable risk, which is the *difference* in the incidence of disease between oral contraceptive users and nonusers. The attributable risk does provide information about the actual occurrence of a disease in the population. For further information, the reader is referred to a text on epidemiological methods. 1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS. a. Myocardial Infarction. An increased risk of myocardial infarction has been associated with oral contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary artery disease such as hypertension, hypercholesterolemia, morbid obesity, and diabetes. The relative risk of heart attack for current oral contraceptive users has been estimated to be two to six. The risk is very low under the age of 30. Smoking in combination with oral contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women in their mid-thirties or older with smoking accounting for the majority of excess cases. Mortality rates associated with circulatory disease have been shown to increase substantially in smokers, especially in those 35 years of age and older among women who use oral contraceptives. Oral contraceptives may compound the effects of well-known risk factors, such as hypertension, diabetes, hyperlipidemias, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and cause glucose intolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see section 9 in WARNINGS). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors. b. Thromboembolism. An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to non-users to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. Cohort studies have shown the relative risk to be somewhat lower, about 3 for new cases and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease associated with oral contraceptives is not related to length of use and disappears after pill use is stopped. A two- to four-fold increase in relative risk of post-operative thromboembolic complications has been reported with the use of oral contraceptives. The relative risk of venous thrombosis in women who have predisposing conditions is twice that of women without such medical conditions. If feasible, oral contraceptives should be discontinued at least four weeks prior to and for two weeks after elective surgery of a type associated with an increase in risk of thromboembolism and during and following prolonged immobilization. Since the immediate postpartum period is also associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than four weeks after delivery in women who elect not to breast feed. c. Cerebrovascular diseases. Oral contraceptives have been shown to increase both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes), although, in general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and non-users, for both types of strokes, and smoking interacted to increase the risk of stroke. In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for non-smokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hypertension. The attributable risk is also greater in older women. d. Dose-related risk of vascular disease from oral contraceptives. A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high density lipoproteins (HDL) has been reported with many progestational agents. A decline in serum high density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the activity of the progestogen used in the contraceptive. The activity and amount of both hormones should be considered in the choice of an oral contraceptive. Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral contraceptive agents should be started on preparations containing 0.035 mg or less of estrogen. e. Persistence of risk of vascular disease. There are two studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40-49 years who had used oral contraceptives for five or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. However, both studies were performed with oral contraceptive formulations containing 50 micrograms or higher of estrogens. 2. ESTIMATES OF MORTALITY FROM CONTRACEPTIVE USE. One study gathered data from a variety of sources which have estimated the mortality rate associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is low and below that associated with childbirth. However, smokers 35 and older and non-smokers 40 and older who use oral contraceptives have a significant increase in mortality higher than those using other methods of birth control. These facts must be weighed in conjunction with failure rates for other methods and the risk associated with subsequent pregnancy. 3. CARCINOMA OF THE REPRODUCTIVE ORGANS. Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. While there are conflicting reports most studies suggest that use of oral contraceptives is not associated with an overall increase in the risk of developing breast cancer. Some studies have reported an increased relative risk of developing breast cancer, particularly at a younger age. This increased relative risk appears to be related to duration of use. Some studies suggest that oral contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors. 4. HEPATIC NEOPLASIA. Benign hepatic adenomas are associated with oral contraceptive use, although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases/100,000 for users, a risk that increases after four or more years of use especially with oral contraceptives of higher dose. Rupture of benign, hepatic adenomas may cause death through intra-abdominal hemorrhage. Studies from Britain have shown an increased risk of developing hepatocellular carcinoma in long-term (>8 years) oral contraceptive users. However, these cancers are rare in the U.S. and the attributable risk (the excess incidence) of liver cancers in oral contraceptive users approaches less than one per million users. 5. OCULAR LESIONS. There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia, papilledema, or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately. 6. ORAL CONTRACEPTIVE USE BEFORE OR DURING EARLY PREGNANCY. Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. The majority of recent studies also do not indicate a teratogenic effect, particularly in so far as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy. The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion. It is recommended that for any patient who has missed two consecutive periods pregnancy should be ruled out before continuing oral contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral contraceptive use should be discontinued until pregnancy is ruled out. 7. GALLBLADDER DISEASE. Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral contraceptive formulations containing lower hormonal doses of estrogens and progestogens. 8. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. Oral contraceptives have been shown to cause a decrease in glucose tolerance in a significant percentage of users. This effect has been shown to be directly related to estrogen dose. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the non-diabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects prediabetic and diabetic women in particular should be carefully monitored while taking oral contraceptives. A small proportion of women will have persistent hypertriglyceridemia while on the pill. As discussed earlier (see WARNINGS 1a and 1d), changes in serum triglycerides and lipoprotein levels have been reported in oral contraceptive users. 9. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in women taking oral contraceptives, and this increase is more likely in older oral contraceptive users and with extended duration of use. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing progestational activity. Women with a history of hypertension or hypertension-related diseases, or renal disease, should be encouraged to use another method of contraception. If women elect to use oral contraceptives, they should be monitored closely and if significant elevation of blood pressure occurs, oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives, and there is no difference in the occurrence of hypertension between former and never users. 10. HEADACHE. The onset or exacerbation of migraine or development of headache with a new pattern which is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause. 11. BLEEDING IRREGULARITIES. Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first three months of use. Non-hormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out. Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was preexistent. 12. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. **PRECAUTIONS:** 1. PHYSICAL EXAMINATION AND FOLLOW UP. A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology, and relevant laboratory tests. In case of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care. 2. LIPID DISORDERS. Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult. 3. LIVER FUNCTION. If jaundice develops in any woman receiving such drugs, the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function. 4. FLUID RETENTION. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention. 5. EMOTIONAL DISORDERS. Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. 6. CONTACT LENSES. Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist. 7. DRUG INTERACTIONS. Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association, though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines. 8. INTERACTIONS WITH LABORATORY TESTS. Certain endocrine and liver function tests and blood components may be affected by oral contraceptives: a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3, increased norepinephrine-induced platelet aggregability. b. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radio-immunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG, free T4 concentration is unaltered. c. Other binding proteins may be elevated in serum. d. Sex-binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids; however, free or biologically active levels remain unchanged. e. Triglycerides may be increased. f. Glucose tolerance may be decreased. g. Serum folate levels may be depressed by oral contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives. 9. CARCINOGENESIS. See WARNINGS section. 10. PREGNANCY. Pregnancy Category X. See CONTRAINDICATIONS and WARNINGS sections. 11. NURSING MOTHERS. Small amounts of oral contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child. **INFORMATION FOR THE PATIENT: See Patient Package Insert.**

ADVERSE REACTIONS: An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS section). Thrombophlebitis and venous thrombosis with or without embolism. Arterial thromboembolism. Pulmonary embolism. Myocardial infarction. Cerebral hemorrhage. Cerebral thrombosis. Hypertension. Gallbladder disease. Hepatic adenomas or benign liver tumors. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea. Vomiting. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Amenorrhea. Temporary infertility after discontinuation of treatment. Edema. Melasma which may persist. Breast changes: tenderness, enlargement, secretion. Change in weight (increase or decrease). Change in cervical erosion and secretion. Diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted: Pre-menstrual syndrome. Cataracts. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiform. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. Hemolytic uremic syndrome. Acne. Changes in libido. Colitis.

OVERDOSAGE: Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea and withdrawal bleeding may occur in females.

HORMONE REPLACEMENT THERAPY

Introduction to steroids in the menopause 1980
Göran Samsioe, MD, PhD
Göteborg, Sweden

Estrogen replacement therapy can lower the incidence of fractures and cardiovascular disease in menopausal women. Adding a progestin to the regimen may prevent some of the side effects of estrogen replacement.

The benefits and risks of hormone replacement therapy: An epidemiologic overview 1986
Susan Harlap, MB, BS
New York, New York

Current epidemiologic knowledge suggests that the benefits of hormone replacement therapy, with or without progestins, strongly outweigh the risks for postmenopausal women.

The effect of sex steroids on the skeleton in premenopausal women 1993
Robert Lindsay, MB, ChE, PhD, FRCP
West Haverstraw and New York, New York

Entering menopause with low bone mass increases the risk of osteoporotic fracture. Although peak bone mass is primarily genetically determined, it can potentially be modified by nutritional and life-style factors that maximize bone mass at menopause.

The role of progestins in hormone replacement therapy 1997
Rogerio A. Lobo, MD
Los Angeles, California

Although the use of unopposed estrogen results in overall lower mortality rates, appropriate sequential addition of low-dose progestins is a viable option in postmenopausal women.

Use of two types of estradiol-releasing skin patches for menopausal patients in a tropical climate 2005
Terry McCarthy, MB, BS, FRCS, FRCOG, Vesna Dramusic, MD, DSc, and Shan Ratnam, MD, FRCS, FRCOG
Singapore

A study of two estradiol-releasing patches found one was better suited for use in the hot, humid climate of Singapore.

Discussion II 2011

American Journal of Obstetrics and Gynecology

Founded in 1920

volume 166 *number* 6 *part* 2 JUNE 1992

Introduction

Daniel R. Mishell, Jr., MD

Los Angeles, California

An important symposium entitled "Steroids from Menarche to Menopause" was held on September 17, 1991, in Singapore at the XIII World Congress of Gynaecology and Obstetrics (International Federation of Gynecology and Obstetrics). Recent epidemiologic information on oral contraceptives and hormone replacement therapy, clinical considerations of hormone therapy, and future therapies were presented by an international faculty.

The first session was devoted to contraceptive steroids, and the second session dealt with the use of steroids after menopause. These topics were chosen because of their importance to women today and because of the great amount of misinformation that has been perpetuated about the dangers of these steroids.

Women in the United States try to avoid unwanted pregnancies for at least one third of their lives and for half of their reproductive lives, particularly between the time of the birth of their last wanted child (average age, 29 years) and the time of menopause. After menopause most women need estrogen replacement therapy for the remainder of their lives.

Oral contraceptive steroids, which have been used for 30 years, provide one of the most effective reversible methods of contraception. Although other options are available, most are not as effective and none are as popular in the United States. In addition, oral contraceptive steroids have many health benefits. Nevertheless, statistics show that a higher percentage of married women in the United States used oral contraceptives 18 years ago than in 1988. The formulations that were used 18 years ago contained higher doses of both estrogen and progestin and were associated with an increased risk of potential adverse effects. It is paradoxic that although safer oral contraceptive formulations are now available to prevent pregnancies, a smaller percentage of married women in the United States use them. The reason for this phenomenon is that most women have many concerns about these steroids. The main concerns that women have about oral contraceptives are as follows: (1) the potential increased risk of developing cancer, particularly breast cancer; (2) a potential adverse effect on the reproductive system that might lead to sterility and endanger future pregnancies; and (3) potential adverse metabolic effects that might lead to heart attacks, stroke, pulmonary emboli, and ultimately death. These concerns and fears are unwarranted. Data presented at this symposium show that the new low-dose steroids are safe and actually provide many noncontraceptive health benefits, including prevention of two lethal cancers (ovarian and endometrial).

The second half of the symposium was devoted to estrogen replacement after menopause. Female life expectancy in both developed and developing countries is increasing, mainly because of better obstetric care. Thus one third of the life of the average woman in the United States occurs after the menopause. This is a time of estrogen deficiency, which poses a wide range of problems. In the United States nearly 35 million women (30% of the female population) are in the postmenopausal age group; thus it is an important topic of public health concern.

The consequences of estrogen deficiency can be categorized as early problems (hot flushes, insomnia, depression, and other psychological symptoms); intermediate consequences, which occur approximately 5 years after the menopause (atrophy of the vagina, uterine prolapse, urgency and stress incontinence, and thinning of the skin); and the most severe consequences of estrogen deficiency, which begin about 10 years after menopause. These severe problems were addressed at this symposium: the development of osteoporotic fractures, which can cause immobilization and death, and the acceleration of atherosclerosis in the coronary arteries and cerebral vessels, which leads to increased incidences of heart attacks and stroke, the number one cause of death in women. These problems can often be delayed or even eliminated by the administration of estrogen.

The studies presented at this symposium demonstrate that steroids are beneficial both to younger women (because they prevent unwanted pregnancy and because of their many noncontraceptive health benefits) and to older women (because they prevent the problems associated with estrogen deficiency). Steroids used in oral contraceptives and estrogen replacement therapy are thus beneficial to a woman's health and longevity.

From the Department of Obstetrics and Gynecology, School of Medicine, University of Southern California.

The safety of oral contraceptives: Epidemiologic insights from the first 30 years

David A. Grimes, MD
Los Angeles, California

Because oral contraceptives are used by tens of millions of healthy women, their safety for short-term and long-term use is an important issue that has been examined in a large number of epidemiologic studies. These studies have become more rigorous and have increased in size and analytic sophistication over the years. Although breast cancer remains the most important safety concern, the bulk of recent data suggests that oral contraceptives have no overall impact on a woman's risk of developing this disease. The results are less clear on the risk of cervical cancer and its precursors because of methodologic problems. However, the newer oral contraceptive formulations no longer appear to be associated with an increased risk of myocardial infarction or stroke. (AM J OBSTET GYNECOL 1992;166:1950-4.)

Key words: Epidemiologic studies, safety, breast cancer, ovarian cancer

Oral contraceptives are one of the most thoroughly studied medications ever used. Because tens of millions of healthy women worldwide have used oral contraceptives during the past 30 years and because some women have used them for extended lengths of time, the safety of short-term and long-term use of these preparations is a public health issue of great importance. Hence a large number of epidemiologic studies have been performed to address this concern. Oral contraceptives confer important health benefits unrelated to contraception which were unsuspected 30 years ago. Recent sophisticated studies have also alleviated concerns about potential cardiovascular and neoplastic risks associated with use of the pill. This review will highlight some of the important epidemiologic findings that concern the safety of oral contraceptives. It will describe the main types of epidemiologic studies that have been performed, summarize information on the established health benefits of oral contraceptives, and comment on several putative risks and lingering concerns.

Types of epidemiologic studies

All epidemiologic studies can be portrayed in a hierarchy of scientific value. The main types of studies can be divided into two categories: observational and experimental. In an observational study the investigator merely observes what happens in clinical practice. In contrast, in an experimental study the investigator intervenes by assigning treatments to subjects.

Observational studies can be further divided into descriptive and analytic studies. Descriptive studies include case reports and case-series reports (several cases in a single report). Descriptive studies, which are often performed to characterize a new disease or persons with a disease, have no comparison group; thus they cannot be used to test hypotheses or to draw conclusions about causation. Their greatest scientific usefulness may be to generate hypotheses that can then be tested in more rigorous studies. An example would be the case-series report that noted the appearance of functional ovarian cysts in women who use multiphasic oral contraceptives.[1]

Analytic studies can be divided into two types: cohort and case-control. In the former women are followed up from the time of exposure (e.g., use of contraception) to outcome (e.g., myocardial infarction). Advantages of cohort studies include the ability to calculate incidence rates, relative risks, and attributable risks. Examples of cohort studies include the Royal College of General Practitioners' study[2] and the Oxford/Family Planning Association study[3] in the United Kingdom and the Nurses' Health Study[4] in the United States. In these prospective studies thousands of women are being followed up from the time of exposure to oral contraceptives.

In contrast to cohort studies, case-control studies look backward in time. The investigator begins with an out-

6/0/37608

come (e.g., myocardial infarction) and looks back in time for exposure (e.g., type of contraception used). Case-control studies have contributed much knowledge about rare events and events that take a long time to develop (e.g., cancer). Unlike cohort studies, however, case-control studies do not enable investigators to calculate incidence rates, relative risks, or attributable risks. Instead investigators calculate odds ratios, which provide a good proxy for relative risks for infrequent diseases. An example of this type of study is the World Health Organization study[5] of the potential association between liver cancer and use of oral contraceptives.

The randomized, controlled trial is clinical medicine's closest approximation to the laboratory scientist's experiment. Use of randomized, controlled trials is the only way to avoid the biases that can undermine analytic studies: selection bias, ascertainment bias, and confounding. However, these trials are often complex and expensive to conduct. Because they rely on volunteers to act as subjects, the results may not be readily extrapolated to broad populations of women. In addition, this type of research poses unique ethical problems. Examples of randomized, controlled trials would be those that compare metabolic effects of different formulations of oral contraceptives.[6]

Established health benefits

Oral contraceptives may be the only prescription drug that increases life expectancy.[7] This benefit is derived from the oral contraceptives' powerful protection against several life-threatening diseases. The most important noncontraceptive health benefit is protection against ovarian cancer. In many developed countries this is the leading cause of death from gynecologic malignancy. Women who use oral contraceptives for as little as 6 months gain significant protection against ovarian cancer.[8] Results from studies around the world have been strikingly consistent; the risk of epithelial cancers of the ovary is reduced by approximately 40%.[9] In the largest case-control study of this phenomenon[8] protection against ovarian cancer lasted a minimum of 15 years after discontinuation of oral contraceptives. The longer a woman used oral contraceptives, the greater the protection gained; after 12 years of use, the risk of developing ovarian cancer was reduced by about 80%.

Protection against endometrial cancer is of the same order of magnitude: around 50%.[9] As is the case with ovarian cancer the protection against endometrial cancer persists for a minimum of 15 years after the last use of oral contraceptives.[10] The protection provided is greatest for those women who are at high risk, namely, nulliparous women. With increasing parity the protection moderates. All three main histologic types of endometrial cancer are reduced in frequency by use of oral contraceptives.[10]

The third life-threatening disease that is reduced in frequency by use of oral contraceptives is pelvic inflammatory disease. Women who take oral contraceptives have only half the risk of being hospitalized for this serious infection compared with women who do not use oral contraceptives.[11] In addition, women who develop pelvic inflammatory disease while they take oral contraceptives tend to have milder infections as judged by laparoscopy.[12] Whether this effect is mediated through changes in cervical mucus, decreased retrograde menstruation, decreased amount of monthly uterine bleeding, or other factors is unknown. Nevertheless the protection is strong and clinically important.

Ectopic pregnancy is the fourth potentially fatal condition that is reduced in frequency by use of oral contraceptives. Women who use oral contraceptives have approximately 90% fewer ectopic pregnancies than women who do not use contraceptives.[13] Without ovulation pregnancy should be impossible in any site.

Four conditions that impair quality of life are also reduced in frequency by use of oral contraceptives. These include iron deficiency anemia, primary dysmenorrhea, functional ovarian cysts, and benign breast disease.[13] The benefit related to this protection is large on an international scale. An alleged increase in the risk of developing functional ovarian cysts among women who do not use multiphasic pills[1] has not been corroborated by national statistics.[14]

In addition, four other protective effects of oral contraceptives have been suggested, although they have not been well established. These include protection against leiomyomata uteri, osteoporosis, toxic shock syndrome, and rheumatoid arthritis. Duration-related protection against leiomyomata was observed in the Oxford/Family Planning Association study.[15] Because this report challenges traditional thinking about the association between oral contraceptives and leiomyomata, this finding requires corroboration. Evidence is controversial about the magnitude and duration of protection against osteoporosis,[16] if it exists. A recent report[17] has found that oral contraceptives provide powerful protection against osteoporosis with longer use affording greater protection. The protection against toxic shock syndrome observed in a number of studies[18] appears to have been mediated through use of less absorbent tampons by women who used oral contraceptives.[13] Evidence remains divided as to protection provided by use of oral contraceptives against rheumatoid arthritis.[19] Alternatively, use of the pill may modify the course of the disease and prevent severe forms from developing.[20]

Potential risks

The single most worrisome question about the safety of oral contraceptive use is its potential effect on the development of breast cancer. During the past three decades many large studies found no overall effect. Authoritative reviews[21] of these studies, including two meta-analyses,[9, 22] have provided a reassuring picture. The aggregate relative risk of developing breast cancer is close to 1.0, with a very narrow 95% confidence interval. However, subgroup analyses have identified increased risks in certain populations, such as women aged 30 to 34 years or those with one child.[2] In general these findings have been inconsistent. In addition, a large case-control study[23] in the United Kingdom found a duration-related increase in the risk of developing breast cancer among young women who had used oral contraceptives, although the authors noted no corroboration from vital statistics of that nation.

In an attempt to replicate these findings, investigators in the United States reanalyzed the world's largest case-control study of this question.[24] Among nulliparous women they noted a suggestion of an increase in risk of developing breast cancer with increasing use of oral contraceptives by young women, but the opposite trend was discovered among older women.[25] This suggests that long-term use of oral contraceptives may promote breast cancer; that is, it may push forward in time the age at which breast cancer is diagnosed in women who are destined to develop the disease without having any net effect on a woman's lifetime risk.

Cervical cancer is a leading cause of cancer deaths in many developing countries. A large number of epidemiologic studies[9] have examined the potential association between use of oral contraceptives and this malignancy. The data are conflicting. In recent years several studies have reported an increased risk of developing cervical cancer among long-term users of oral contraceptives, for example, after 5 years of use.[25] It cannot be determined whether this reflects a causal relationship, because the study of cervical cancer poses serious methodologic challenges. For example, diagnostic bias is often a problem because women who use oral contraceptives are more likely to have regular cytologic screening than other women. The confounding effects of sexual behavior and cigarette smoking have not been adequately addressed in many studies. Nevertheless, it appears prudent to recommend that women who take oral contraceptives have cytologic screening a minimum of one time each year.

Liver cancer is another malignancy of great importance in the developing world. During the 1980s three case-control studies[9] from the United States and United Kingdom reported an increased risk of developing liver cancer among women who used oral contraceptives. However, a large case-control study[5] performed in developing countries by the World Health Organization found no increase in the risk of developing liver cancer with increasing duration of oral contraceptive use. Moreover, in developed countries no change in mortality rates among women from liver cancer has occurred despite extensive use of oral contraceptives during the past three decades.

Cardiovascular disease is the leading cause of death among women in many parts of the world. Whereas early epidemiologic studies[9] of high-dose oral contraceptives found significantly increased risks of developing cardiovascular disease among users of the pill, several trends have led to a reassessment of that risk. First, studies have become more sophisticated and now take into account the potentially confounding effects of cigarette smoking. Second, in recent years women have been evaluated more carefully before they begin to take oral contraceptives, and those women who have serious underlying medical problems and older women who smoke have been less likely to use oral contraceptives. Third, the formulations of oral contraceptives have changed dramatically; current formulations have a three- to fourfold decrease in estrogen dose and a 10-fold decrease in progestin dose compared with the formulations initially prescribed. Hence the findings of early epidemiologic studies are likely irrelevant to today's preparations.

Use of oral contraceptives by healthy women who do not smoke does not appear to be associated with an increased risk of either myocardial infarction or stroke. Data from the United States[27, 28] and the United Kingdom[3] have documented no increase in the risk of death from cardiovascular disease among contemporary users of oral contraceptives. Data from the Oxford/Family Planning Association study[29] also support the hypothesis that oral contraceptives that contain less than 50 μg of estrogen are safer than higher-dose formulations.

Some evidence suggests that the pathophysiology of myocardial infarction among women who used oral contraceptives in earlier studies was thrombosis. First, most studies, including the large Nurses' Health Study[4] from the United States, have found no increased risk of myocardial infarction among former users of oral contraceptives. If atherosclerosis were the cause then the risk should remain elevated after discontinuation of oral contraceptives. Corroborating evidence comes from autopsy studies of women who have died of myocardial infarction.[30] Second, there does not appear to be a duration-related effect between length of oral contraceptive use and risk of infarction.[28] This also argues against deposition of plaque as the pathophysiology. Third, studies performed in monkeys have demonstrated significant protection against the development of coronary atherosclerosis in animals who were given high progestin-dose combination oral contraceptives

that altered their lipid levels adversely.[31] This suggests that the estrogen in oral contraceptives may have a direct protective effect on the wall of the coronary vessels analogous to the protection against coronary artery disease provided by estrogen replacement therapy given to postmenopausal women.

The damaging effect of smoking has been clarified in recent years. In the Royal College of General Practitioners' study[32] the risk of myocardial infarction has been analyzed by amount of smoking and use of oral contraceptives. Current users of oral contraceptives who did not smoke had no increased risk of infarction. Current users of oral contraceptives who smoked fewer than 15 cigarettes a day had more than a threefold increase in risk. On the other hand, current users of oral contraceptives who smoked 15 or more cigarettes a day had a 21-fold increase in risk, a powerful synergistic effect. The consensus is clear: oral contraceptives are safe, and smoking is dangerous. It has been wryly noted that a strong case can be made on public health grounds for making oral contraceptives available over the counter and cigarettes available on prescription only.

In addition to the risk of developing cancer and cardiovascular disease, a third concern women have about oral contraceptives is potential infertility after discontinuation of the pills. In the Oxford/Family Planning Association study[33] the resumption of fertility after discontinuing oral contraceptives was similar to resumption of fertility after discontinuation of other methods of contraception, although a transient delay was found. A recent analysis[34] of this question in the United States also confirmed a temporary delay of about 2 months on average in return of fertility. This delay was dose related. Lower-dose pills were associated with a shorter delay than were higher-dose pills.

The current status

In summary, recent, large, and sophisticated epidemiologic studies around the world have provided an encouraging assessment of oral contraceptives. Oral contraceptives protect against the development of ovarian and endometrial cancers, pelvic inflammatory disease, and ectopic pregnancy; they also protect against the development of iron deficiency anemia, primary dysmenorrhea, functional ovarian cysts, and benign breast disease. Most studies show no overall effect on the risk of developing breast cancer. The potential effect of long-term oral contraceptive use on breast cancer remains controversial and will require further evaluation. Although several studies have suggested an increased risk of developing cervical neoplasia with long-term oral contraceptive use, methodologic difficulties preclude drawing conclusions about causality. Nevertheless, women who use oral contraceptives should have routine cytologic screening. Several lines of evidence argue against an association of oral contraceptive use with liver cancer.

The increased risk of developing cardiovascular disease among women who use oral contraceptives in older studies does not appear to relate to contemporary oral contraceptive use. In recent studies neither current nor previous oral contraceptive use has been shown to increase the risk of myocardial infarction or stroke. Atherosclerosis does not appear to be an important cause of myocardial infarction in women who use oral contraceptives. Finally, a transient delay in return of fertility can occur after use of oral contraceptives is discontinued, although the effect is lessened in women who use low-dose oral contraceptives.

When future medical historians look back on the twentieth century, the development of oral contraceptives will stand out as a landmark medical achievement. Like antibiotics, oral contraceptives are life-saving medications. Their use worldwide has averted much morbidity and mortality related to unintended pregnancy. Moreover, when used by healthy women, the noncontraceptive benefits outweigh the risks involved. To paraphrase William Foege, MD, former director of the Centers for Disease Control, "This may be the most noble medicine of all . . . the anonymous gift of health."

Clinical and metabolic considerations of long-term oral contraceptive use

Ian F. Godsland, BA, David Crook, PhD, and Victor Wynn, FRCP, FRCPath
London, United Kingdom

Newer lower dose formulations are associated with an improved cardiovascular disease risk marker profile, which supports their use for longer periods and among older women. Epidemiologic studies of the newer formulations are limited. Without clinical information, an evaluation of the effects of more recent formulations on metabolic risk markers for cardiovascular disease is useful. In a large cross-sectional study, a reduction in the progestin dose and use of alternative progestins substantially reduced the proportion of oral contraceptive users with values associated with an increased risk of cardiovascular disease. No progression in metabolic changes was found by analyzing the effect of the duration of oral contraceptive use. The user's age interacted positively with the oral contraceptive–induced increase in serum triglyceride levels, but there was no interaction of age with the oral contraceptive's effect on oral glucose tolerance, glucose and insulin responses, low-density lipoprotein cholesterol, or high-density lipoprotein subfraction 2 cholesterol levels. (Am J Obstet Gynecol 1992;166:1955-63.)

Key words: Cardiovascular disease, progestins, metabolic risk markers.

With the introduction of low-dose oral contraceptives and more selective progestins such as desogestrel, gestodene, and norgestimate, the possibility now exists that duration of oral contraceptive use may be prolonged and that oral contraceptive use may be extended to women older than age 35 years. Such use raises specific issues of oral contraceptive safety. Questions to be addressed include whether extending the duration of continuous oral contraceptive use would result in a commensurate increase in any possible risks and whether older women are at increased risk for adverse effects associated with oral contraceptive use compared with their younger counterparts.

Recommendations against the use of combination oral contraceptives in women older than 35 years are based on findings from some epidemiologic studies performed during the 1970s, principally the Royal College of General Practitioners' Oral Contraceptive Study.[1, 2] This study found that cardiovascular disease was the principal adverse consequence of oral contraceptive use, with risk associated in women older than 35 years who were smokers. Most oral contraceptive formulations included in this and other epidemiologic studies contained 50 μg or more of estrogen. Currently support exists for extending combined oral contraceptive use in older women based on the recognition that, as a result of the introduction of new, lower dose formulations, the risks are likely to have been significantly reduced since the original studies were performed.

Long-term oral contraceptive use and cardiovascular disease

Studies of the older medium- and high-dose formulations still provide our only reliable information on long-term oral contraceptive safety and should be taken into account when considering issues related to currently used formulations. Not all studies examined the interactions of duration of use and age of user with risk of cardiovascular disease. Those studies[3-9] that showed a positive association between current oral contraceptive use and cardiovascular disease and that specifically addressed interactions with age and duration are listed in Table I.

Effects of duration of oral contraceptive use. In the case-control study of mortality from myocardial infarction by Mann et al.,[3, 4] most patients who took oral contraceptives had used them for 2 or more years. Other case-control studies have provided no evidence of an interaction of duration of use with cardiovascular disease risks associated with current oral contraceptive use. Likewise, prospective studies have provided little evidence of an effect of duration or use. The 1977 Royal College of General Practitioners' Oral Contraceptive Study described an increased risk of cardiovascular disease with increasing duration of use,[8] but this was not confirmed in subsequent reports.[1, 2] There was also no evidence of increased risk of cardiovascular disease with prolonged duration of oral contraceptive use in cases in the Oxford/Family Planning Association Cohort.[9]

Effects of age of oral contraceptive user. The case-control study of mortality from myocardial infarction of Mann et al.[3, 4] found increased risk of coronary heart

disease in women aged 40 to 44 years compared with their younger counterparts. However, the case-control study of survivors of a myocardial infarction of the Boston University Drug Epidemiology Unit[5, 6] found no increased risk in older compared with younger oral contraceptive users. The concern about a correlation between the user's age and the risk associated with oral contraceptive use stems largely from the findings of the Royal College of General Practitioners' Oral Contraceptive Study. In the 1977 report on this study, a rate ratio of 2.0 was found for mortality from vascular disease in women aged 25 to 34 years who had ever used oral contraceptives, whereas the corresponding rate for users aged 35 to 44 years was 4.5.[8] In the 1981 report on this study, the corresponding figures were 1.6 and 3.3, respectively, among nonsmokers and 3.4 and 4.2 among smokers.[1] In the 1983 report on arterial disease, the corresponding figures were 1.5 and 1.8, respectively, among nonsmokers and 1.6 and 3.1 among smokers.[2] In the Oxford/Family Planning Association Study most cases of vascular disease were in women older than 35 years of age.[10]

Effects of previous oral contraceptive use. An important question in long-term oral contraceptive use is whether there is an increased risk of cardiovascular disease in women who are not current users but who have used oral contraceptives in the past. None of the case-control studies that demonstrated an increased risk in current users and in which risk in a past-user group was examined showed an increased risk of cardiovascular disease in previous users. However, only one[6] of these studies was specifically designed to investigate the effects of past use.

Among prospective studies, a past-use effect was apparent for cerebrovascular disease but not for ischemic heart disease in the Royal College of General Practitioners' Oral Contraceptive Study.[1] The Nurses' Health Study[11] found some evidence of an increased risk of cerebrovascular disease with increasing duration of previous oral contraceptive use, although this relationship was not significant. In the Oxford/Family Planning Association Study,[9] increased risk of mortality from ischemic heart disease was concentrated among past users, but the authors noted that these women had generally stopped using oral contraceptives because they developed side effects.

Three studies have addressed the issue of a past-use effect in detail. In a case-control study from the Boston University Drug Epidemiology Unit, Slone et al.[6] noted a significant trend in increasing risk of myocardial infarction with duration of previous high-dose oral contraceptive use in women aged 40 to 49 years. This finding was not confirmed by the Nurses' Health Study[11] or by a subsequent study by Rosenberg et al.[12] The design of the last study reproduced that of the earlier study by Slone et al., and they concluded that the absence of a past-use effect could have reflected the change toward lower dose oral contraceptives and more selective prescribing.

Metabolic risk markers for cardiovascular disease in long-term oral contraceptive use

Information on cardiovascular disease risks associated with the use of oral contraceptives containing less than 50 μg of estrogen is limited, although the available data suggest that risks may have been reduced.[13, 14] Little is known of how the user's age or duration of use interact with any risks associated with these low-dose formulations. The risks associated with low-dose oral contraceptives containing the newly synthesized progestins must also be evaluated.

The difficulties in performing effective epidemiologic studies on the effects of oral contraceptive use and the length of time needed before potential side effects can be confirmed have favored the use of alternative methods of evaluating long-term oral contraceptive safety. The most important method has been the investigation of oral contraceptive–induced bio-

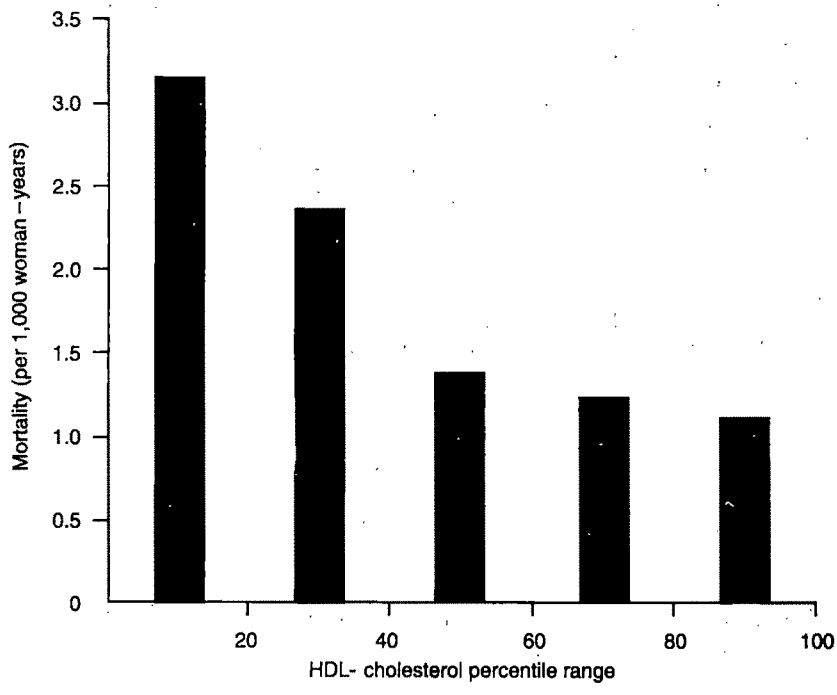

Fig. 1. Mortality from cardiovascular disease by HDL-cholesterol percentile in 3417 women. (Modified from Jacobs DJ, Mebane I, Bangdiwala S, Criqui M, Tyroler H. High density lipoprotein cholesterol as a predictor of cardiovascular disease mortality in men and women: the follow-up study of the Lipid Research Clinics Prevalence Study. Am J Epidemiol 1990;131:32-47.)

chemical alterations, primarily in lipid and carbohydrate metabolism. These disturbances resemble those seen in individuals at increased risk of cardiovascular disease. For example, in Fig. 1, data from the Lipid Research Clinics Prevalence Study show that in passing from the top to the bottom quintile of high-density lipoprotein (HDL) cholesterol concentrations, there is a threefold increase in cardiovascular disease risk in women.[15] Variation in the HDL subfraction 2 (HDL_2) appears to be particularly important with regard to cardiovascular disease risk.[16] Using data from our recent large cross-sectional study,[17] we have derived HDL_2-cholesterol concentration quintile ranges for women who do not take oral contraceptives ($n = 418$) and determined the prevalence of women taking a commonly used combination oral contraceptive formulation (150 μg of levonorgestrel + 30 μg of ethinyl estradiol) occurring in each quintile. Prevalence ratios in each HDL_2-cholesterol quintile are shown in Fig. 2. There was a fourfold greater incidence of observed than expected oral contraceptive users in the lowest HDL_2-cholesterol quintile, the quintile associated with the greatest risk of cardiovascular disease.

The plasma insulin concentration also provides an indicator of cardiovascular disease risk. Elevated insulin concentrations are associated with potentially atherogenic changes in the arterial wall,[18] elevated blood pressure,[19] and reduced fibrinolytic activity.[20] Hyperinsulinemia is also associated with insulin resistance, which was recently identified as a common factor in several biochemical disturbances seen in persons at increased risk of cardiovascular disease.[21] These biochemical disturbances include impaired glucose tolerance, low HDL-cholesterol concentrations, high low-density lipoprotein (LDL) cholesterol concentrations, hypertension, and hypertriglyceridemia. Epidemiologic studies of the association between insulin concentrations and cardiovascular disease are limited, and reliable information has only been obtained from studies in men.[22, 23] Nevertheless, as shown in Fig. 3, it is likely that a substantial increase in cardiovascular disease risk will occur with increasing insulin concentrations. In the Helsinki Policemen Study, the incidence of coronary heart disease increased fivefold in the 10% of individuals with the highest insulin concentrations during an oral glucose tolerance test (OGTT) compared with those in the lowest quintiles of insulin concentration.[23] We defined comparable percentile ranges for OGTT insulin response in 346 women who did not take oral contraceptives and determined the prevalence of women taking the low, fixed-dose levonorgestrel combination in each range (Fig. 4). A fourfold increase occurred in the proportion of oral contraceptive users in the top tenth percentile, the percentile associated with the greatest increase in coronary heart disease risk.

Whether oral contraceptive–induced metabolic disturbances affect the incidence of cardiovascular disease in women who use oral contraceptives is unknown. Al-

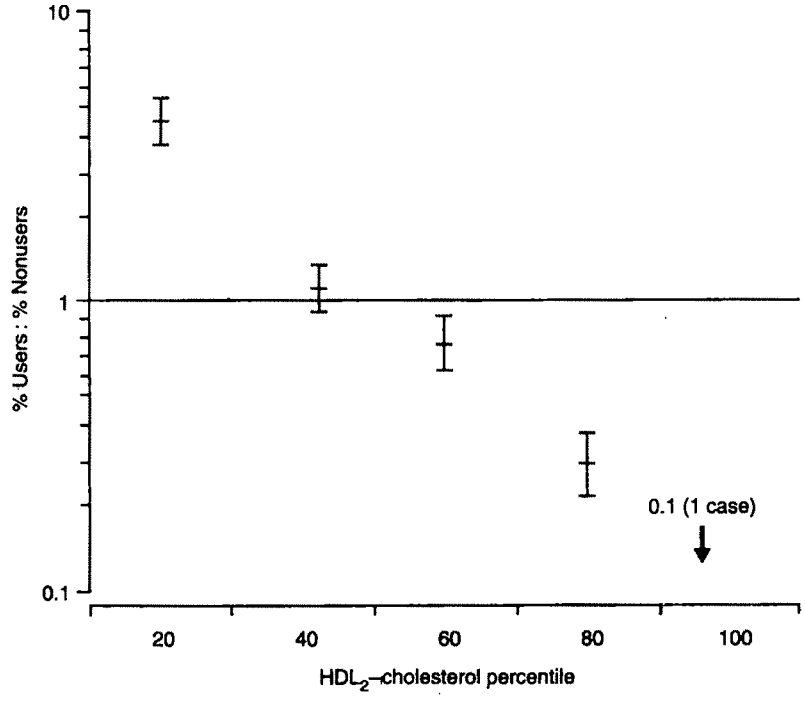

Fig. 2. Prevalence ratios and confidence intervals for 286 users of an oral contraceptive formulation (30 μg of ethinyl estradiol ± 150 μg of levonorgestrel) in HDL_2 cholesterol concentration percentile ranges defined in 418 nonuser control subjects.

though the information from epidemiologic studies is limited, it is advisable to minimize these disturbances if possible. This can be achieved by reducing the estrogen and progestin doses. It may also be possible to reduce the metabolic impact by using alternative oral contraceptive steroids. This is the underlying principle for the development and introduction of the new generation of progestins, which include desogestrel, gestodene, and norgestimate. These progestins have been selected for their lack of androgenic or antiestrogenic properties, which leads to a reduction in potentially adverse biochemical effects, particularly with regard to HDL cholesterol.

In our cross-sectional study, variation in HDL-cholesterol concentrations was primarily caused by variation in the HDL_2 subfraction.[17] The percentage differences between mean values for both HDL-cholesterol and HDL_2-cholesterol in nonuser control subjects and oral contraceptive users, who were taking one of seven different combined formulations, demonstrated a marked effect of the reduction in progestin dose, particularly with the levonorgestrel formulations. The effect of using alternative progestins was also apparent: lower mean values were generally found among women who used the low-dose norethindrone and desogestrel combinations. These findings were also the case when OGTT insulin responses were compared between the different formulations. We further analyzed the frequency distributions for these variables in the different oral contraceptive groups compared with the distribution in nonusers. The results indicate that reductions in metabolic impact apparent in the differences between means are also apparent in the differences in the proportion of outlying values.[24] Thus the lower HDL_2-cholesterol concentrations in users of fixed-dose levonorgestrel-containing formulations compared with nonusers were the result of an increase in the proportion of abnormally low HDL_2-cholesterol concentrations. As indicated earlier, such outlying values may be associated with an increased risk of coronary heart disease.

These observations clearly demonstrate that a reduction in the steroid dose of oral contraceptives and use of alternative progestins can markedly reduce potentially adverse metabolic changes, even among users of low-dose formulations. Thus extending oral contraceptive use among older women and prescribing oral contraceptives for longer periods may be appropriate.

Just as it was possible to assess interactions of duration of oral contraceptive use and age of the user with

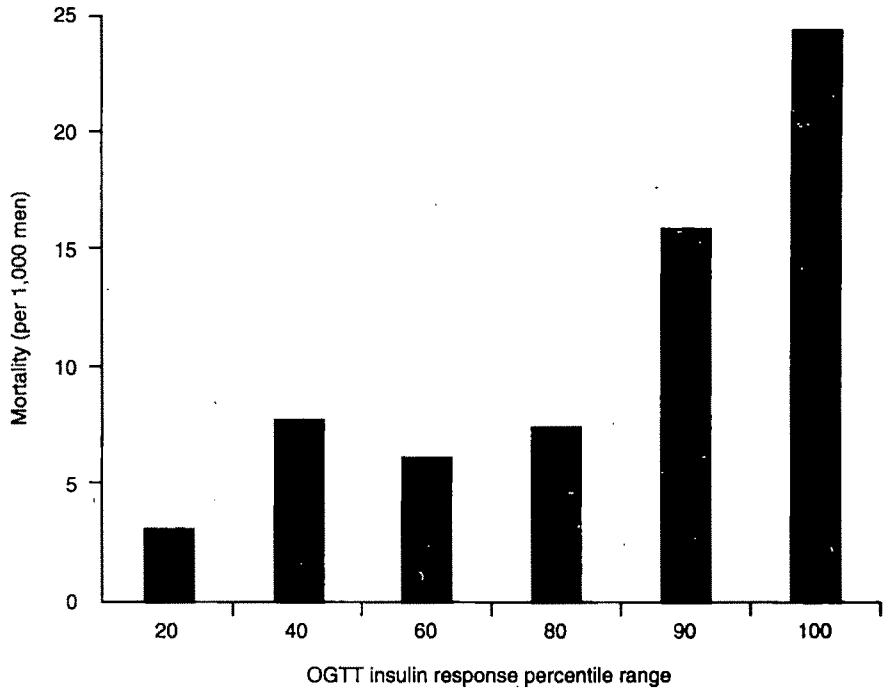

Fig. 3. Mortality from coronary heart disease OGTT insulin area percentile in 982 men. (From Pyörälä K, et al. Acta Med Scand 1985;701(suppl):38-52.)

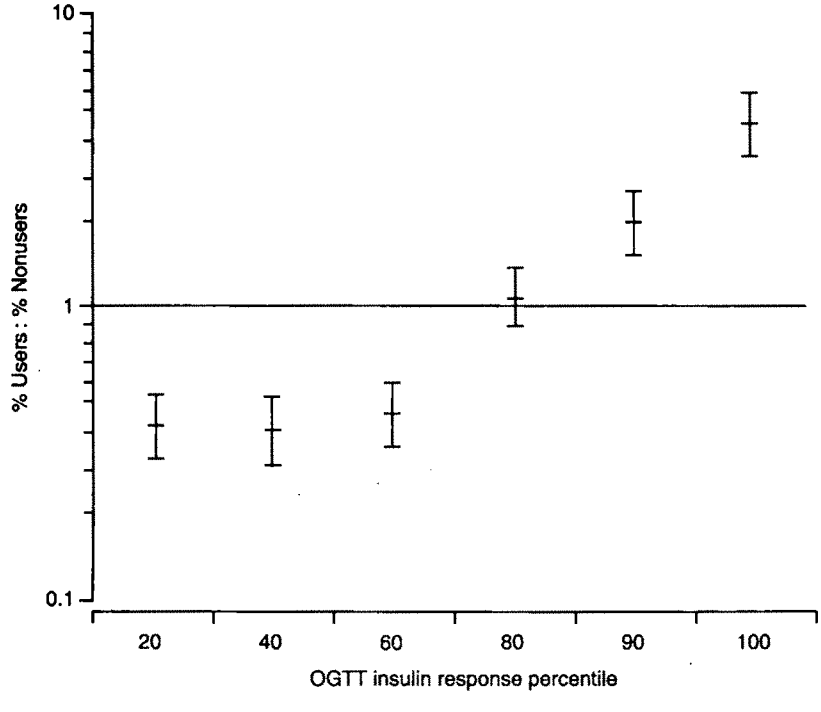

Fig. 4. OGTT incremental insulin area prevalence ratios and confidence intervals for 215 users of an oral contraceptive formulation (30 μg of ethinyl estradiol ± 150 μg of levonorgestrel) in percentile ranges defined in 346 nonuser control subjects.

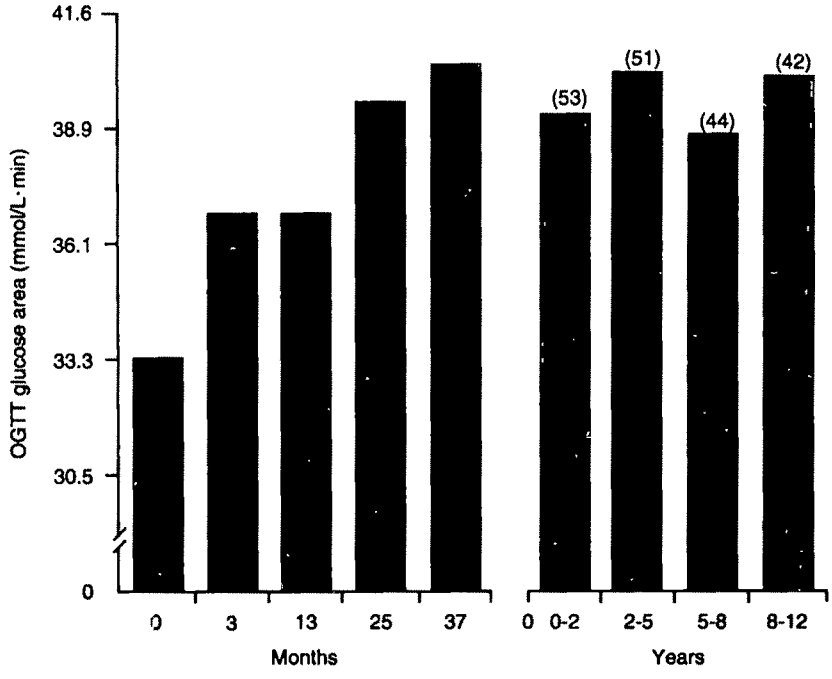

Fig. 5. OGTT glucose area in 17 oral contraceptive users followed up for 37 months *(left)* and in groups of oral contraceptive users (number in parentheses) who have been taking oral contraceptives for up to 2, 5, 8, and 12 years *(right)*. (Data from Wynn V. AM J OBSTET GYNECOL 1982;142:739-46.)

risk of cardiovascular disease in early epidemiologic studies, it should also be possible to assess the interactions of these same two factors with disturbances in metabolic risk markers. Few metabolic studies have addressed these issues, but with the large body of data from our recent cross-sectional study, an analysis of the effects of these factors has been possible.

Effects of duration of oral contraceptive use. Longitudinal studies of the metabolic effects of oral contraceptives have generally been short (<18 months) and have not included sufficient numbers of patients to distinguish significant effects from the considerable intraindividual variability that exists in metabolic variables. An exception was the study by Wynn,[25] who found that in a group of women taking a commonly used combination oral contraceptive (150 μg of levonorgestrel + 30 μg of ethinyl estradiol), deterioration in glucose tolerance progressed with time for up to 3 years. In this study 173 women were tested before and 3 months after they took the oral contraceptive; 86 of these women were tested after 15 months, 39 after 25 months, and 17 after 37 months. Results for the 17 women in the longest series are summarized in Fig. 5, which shows the progressive increase in the area under the OGTT glucose concentration profile with increasing duration of oral contraceptive use. After the initial oral contraceptive–induced elevation in the OGTT insulin response, there was no such progressive change. The initial progression in deterioration in glucose tolerance seen with this levonorgestrel formulation was not seen with a norethindrone-containing, low-estrogen dose formulation.[26]

In our cross-sectional study we further examined the effect of duration of oral contraceptive use in women who were current users of the same fixed-dose, levonorgestrel-containing formulation that was studied in the earlier longitudinal study (150 μg of levonorgestrel + 30 μg of ethinyl estradiol). We divided the users into approximately equal groups according to increasing duration of continuous oral contraceptive use. Mean OGTT glucose areas in women taking oral contraceptives from 3 months to 2 years, from 2 to 5 years, from 5 to 8 years, and from 8 to 12 years are shown in Fig. 5. Results have been standardized for several confounding variables, including age and percentage of ideal body weight. No continuing deterioration in glucose tolerance was seen from 2 to 12 years of use. Similar analyses for OGTT insulin area, fasting serum triglyceride levels, LDL cholesterol, and HDL_2 cholesterol (results not shown) showed no progression with increasing duration of oral contraceptive use.

Effects of age of oral contraceptive user. If the age of the oral contraceptive user is a factor in the degree of metabolic disturbance induced by an oral contraceptive, then a different relationship between age and metabolic variables will be seen in users and nonusers.

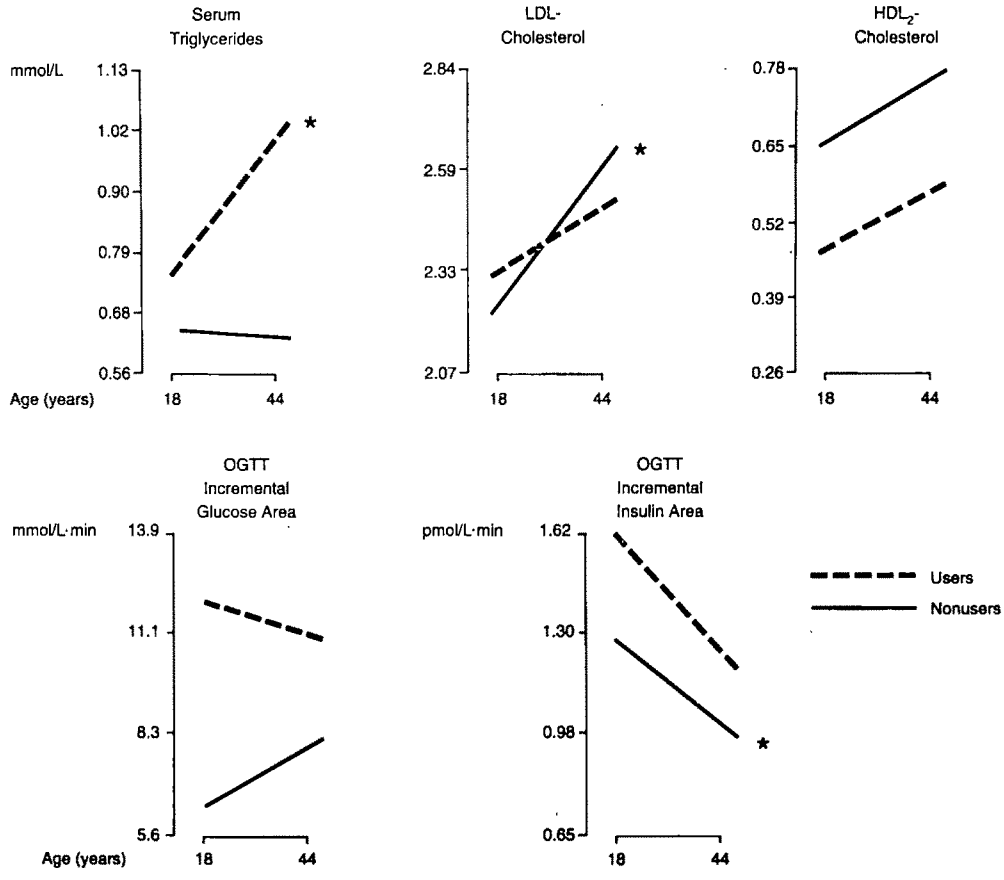

Fig. 6. Regression lines for age (18 to 44 years) with serum triglycerides, LDL and HDL_2 cholesterol and OGTT incremental glucose and insulin areas in nonusers (n = 418, lipids and lipoproteins; n = 296, glucose and insulin) and oral contraceptive users (n = 346, lipids and lipoproteins; n = 215, glucose and insulin). *Significant associations ($p < 0.05$.)

Table II. Age, percentage of ideal body weight, glucose area, OGTT insulin area, fasting serum triglycerides, LDL, and HDL_2 for women not currently using oral contraceptives who had never used them (never users) or who had used them in the past (former users)

Variables	*Never User (n = 67)*	*Former user (n = 209)*
Age (yr)	31.1 ± 7.9	32.3 ± 6.6
% Ideal body weight	100.8 ± 10.1	98.6 ± 9.5
OGTT glucose area (mmol/L · min)	35.8 ± 5.0	36.0 ± 5.5
OGTT insulin area (pmol/L · min)*	1629 − 587 + 917	1422 − 474 + 710†
Triglycerides (mmol/L)*	0.71 − 0.22 + 0.32	0.66 − 0.20 + 0.28
LDL (mmol/L)	2.49 ± 0.83	2.47 ± 0.70
HDL_2 (mmol/L)	0.64 ± 0.24	0.75 ± 0.31‡

Mean ± standard deviation.
*Logarithmically derived data.
†$p < 0.05$, ‡$p < 0.01$, by unpaired t test.

We addressed this issue by deriving the linear regression equations for age with fasting serum triglycerides, LDL and HDL_2 cholesterol, and OGTT glucose and insulin incremental areas with standardization for a number of confounding variables including current and previous cigarette smoking, percentage of ideal body weight, family histories of heart disease and diabetes, alcohol intake, and exercise habit. The analyses were performed for nonuser controls and for women taking the low, fixed-dose levonorgestrel monophasic combination (150 μg of levonorgestrel + 30 μg of ethinyl estradiol); this was the largest group we studied. The regression lines over the range of ages studied (18 to 44 years) are shown in Fig. 6. A marked interaction

was apparent between age and oral contraceptive use with regard to the oral contraceptive–induced rise in fasting serum triglyceride levels; triglyceride levels increased with age in oral contraceptive users but not in nonuser control subjects. However, with LDL cholesterol there was somewhat less of an effect of age in oral contraceptive users than in the nonusers, and there was no difference in interaction with age between users and nonusers with regard to HDL_2 cholesterol. There was also somewhat less of an effect of age in oral contraceptive users with regard to glucose tolerance and no difference between users and nonusers with regard to OGTT insulin response.

Effect of previous oral contraceptive use. In our cross-sectional study, 276 women who were not current oral contraceptive users claimed to have accurate recall of their previous contraceptive history. Of these, 67 had never used oral contraceptives and 209 had used oral contraceptives previously but had not taken oral contraceptives for at least 3 months (mean, 46.3 months). Metabolic variables were compared between never users and former users (Table II).

The only significant differences between never users and former users were in OGTT insulin response and HDL_2 cholesterol. With standardization for age and percentage of ideal body weight, the difference in insulin response was no longer significant, and with standardization for alcohol intake, the difference in HDL_2 cholesterol was no longer significant. Therefore there was no residual effect of previous oral contraceptive use on metabolic variables apparent in the group of former users we studied.

Conclusion

Epidemiologic studies of the older oral contraceptives with high and medium does of estrogen suggest that women older than age 35 years are at higher risk of cardiovascular disease from oral contraceptive use than their younger counterparts. Evidence for an effect of duration of oral contraceptive use or a past-use effect with these agents has not been confirmed.

We found no apparent progression in metabolic risk markers for cardiovascular disease beyond 2 years of continuous oral contraceptive use. There was no potentially adverse interaction between the age of the user and the duration of use and the oral contraceptive's effects on OGTT glucose and insulin areas, LDL cholesterol, and HDL_2 cholesterol. Older women who used oral contraceptives, however, appeared to have appreciably higher triglyceride concentrations than younger oral contraceptive users or nonusers of the same age. Furthermore, no effect of previous oral contraceptive use was apparent in former users.

These considerations support a cautious extension of oral contraceptive use among women older than 35 years of age. However, regular health checks and measurement of serum lipid levels would be desirable.

The efficacy and tolerability of norgestimate/ethinyl estradiol (250 μg of norgestimate/35 μg of ethinyl estradiol): Results of an open, multicenter study of 59,701 women

Benno Runnebaum, MD, K. Grunwald, MD, and T. Rabe, MD
Heidelberg, Germany

The efficacy and tolerability of a new oral contraceptive, norgestimate/ethinyl estradiol (250 μg of norgestimate/35 μg of ethinyl estradiol; Cilag GmbH Research, Sulzbach, Germany) were examined in an open-label study of 59,701 women who were evaluated during 342,348 menstrual cycles; 42,022 women completed the planned treatment regimen of six cycles. A use-efficacy (overall) Pearl index of 0.25 pregnancies per 100 woman-years was calculated based on 342,348 cycles. Tolerability was assessed for all women who completed six treatment cycles. Reductions in mean cycle length and duration of bleeding were noted; 32% of the women experienced reductions in the intensity of bleeding by the end of cycle 6. After six cycles of use, amenorrhea occurred in 1%, spotting in 4%, and breakthrough bleeding in 3% of the participating women. Treatment with norgestimate/ethinyl estradiol had minimal effects on weight, blood pressure, pulse, lipid metabolism, and blood glucose. Adverse effects (acne, nausea, or headaches) occurred at low frequencies and in many cases, were reduced compared with pretreatment levels. The results of this large-scale open trial were comparable with results from two other multicenter trials of the same formulation. (AM J OBSTET GYNECOL 1992;166:1963-8.)

Key words: Norgestimate, ethinyl estradiol, progestins, oral contraceptives

In recent years, much research has focused on the development of oral contraceptives with reduced hormone content.[1] Both the estrogen and progestin components of oral contraceptive formulations are thought to contribute to minor adverse effects, such as nausea, headache, and bleeding irregularities[1] and to more serious health problems, such as an increased risk of cardiovascular disease noted with high-dose formulations.[2-4]

Among the minor adverse effects, nausea and headache are generally linked to estrogen dose. With the introduction of oral contraceptive preparations with estrogen doses of 50 μg or less, the incidence of these adverse effects has generally been reduced.[1] However, breakthrough bleeding (BTB) and spotting, which appear to be determined by the estrogen/progestin ratio, have been more difficult to address.

Most of the early studies suggested that the estrogen content of oral contraceptives was related to venous but not to arterial thromboembolic disease.[5] This finding led to investigation of the influence of the progestin component of oral contraceptives on various risk factors for occlusive arterial disease. In general, estrogen has a favorable effect on cholesterol fractions: it is associated with a reduction in serum concentration of low-density lipoprotein cholesterol and an increase in high-density lipoprotein cholesterol, as well as in the high-density lipoprotein subfraction, HDL_2. All progestins now in clinical use, however, oppose the effects of the estrogen component.[6]

Thus in recent years, one goal of oral contraceptive research has been the development of a highly selective progestin with specific and potent progestational activities and minimal or no androgenic effects.[6] Norgestimate (NGM), a progestin with marked progestational activity and a relative lack of androgenic activity, is promising in this regard.[7] Orally administered NGM is rapidly absorbed, reaches peak blood levels within 30 minutes to 2 hours, and has a plasma half-life of 6 to 14 hours. In the laboratory NGM has been extensively studied. NGM and its major metabolite 17-deacetyl norgestimate contribute to the biologic response.[8]

In previous clinical trials, the efficacy and safety of NGM/ethinyl estradiol (EE) (250 μg of NGM/35 μg of EE; Cilest, Cilag GmbH Research, Sulzbach, Germany; Ortho-Cyclen, R. W. Johnson Pharmaceutical Research Institute, Raritan, N.J.) have been established.[6, 9] The current open-label trial, which enrolled 59,701 women, for a planned treatment period of six cycles, was designed to generate additional data on the efficacy and tolerability of NGM/EE, with special emphasis on changes in bleeding and in metabolic parameters.

Methods

Study design. The trial was an open-label, noncomparative study with a large patient population. The planned length of active treatment was six cycles.

Patient selection. Women of childbearing age who were in good general health and had regular menstrual cycles of approximately 28 to 32 days' duration (including 3 to 5 days of bleeding) were eligible for entry. Exclusion criteria included: (1) the presence of vascular or hematologic disorders such as acute or chronic thromboembolism, cerebrovascular illness, myocardial infarction, or sickle cell anemia; (2) the presence of reproductive disorders such as amenorrhea, a history of herpes gestationis, or severe pruritus during pregnancy; (3) suspected or current pregnancy; and (4) general medical problems such as liver or gallbladder disease, cancer, or other metabolic derangements.

Data collection. Data gathered during the initial visit included age, height, and weight, as well as information on smoking habits, alcohol consumption, gynecologic history (including previous contraceptive use), family medical history, and the use of other concurrent medications.

During the study, information on the cycle (including cycle length, duration and intensity of bleeding, lack of bleeding during tablet-free interval, occurrence of spotting or BTB, dysmenorrhea, and other gynecologic findings) was recorded by each patient on her study calendar, which she brought with her to the checkup examinations after the third and sixth cycles.

Clinical variables measured during office visits before treatment and after the third and sixth cycle included blood pressure, pulse, and body weight. Concomitant symptoms, such as acne, nausea, breast tension, headaches, or other, were recorded by the patient on her study calendar. Reports on adverse symptoms were elicited by a questionnaire.

Laboratory variables, including serum cholesterol, serum triglyceride, and blood and urinary glucose levels, were evaluated in a subgroup of 3000 women before the study and after the third and sixth cycles.

Evaluation of data. The efficacy of NGM/EE was based on the computation of the overall Pearl index[10] for the entire study population and the related 95% confidence intervals, which were computed under the assumption of Poisson-distribution data.[11] Tolerability was evaluated by tabulating data on the menstrual cycle, adverse experiences, routine physical findings, and measurements of serum cholesterol, triglyceride, blood glucose, and urinary glucose levels for patients who completed cycle 6 of treatment with NGM/EE.

Results

Premature termination. During the study, 59,701 patients were enrolled by 1609 physicians. Treatment was discontinued prematurely in 6588 patients (11%). Terminations were at the physicians' request, at the patients' request, or were the result of a joint decision (Table I).

Patient characteristics. Among the 59,701 women who received NGM/EE, mean (± standard deviation) age was 24.0 ± 6.7 years, mean height was 166.4 ± 6.3 cm, mean weight was 61.2 ± 9.0 kg, and mean Broca index was 103.0% ± 23.3% (Broca index = body weight/0.9 × [height/100]). The mean (± standard deviation) age at menarche was 12.9 ± 1.3 years. Before they received NGM/EE, 88% of the women had a regular menstrual cycle (i.e., range, 24 to 32 days). Among women with regular cycles, the mean (± standard deviation) duration of the cycle was 28.0 ± 2.2 days, and the mean duration of bleeding was 4.9 ± 1.3 days. The intensity of the bleeding was designated as normal by 74% of the women, light by 13%, and heavy by 14%. Of the study subjects, 14% reported inter-

Table I. Persons responsible for decisions to withdraw from treatment, by cycle

Cycle	*Physician*	*Patient*	*Both*	*Unknown*	*Totals (%)*
1	87	300	59	70	516 (7.8)
2	91	428	62	54	635 (9.6)
3	397	1909	258	193	2757 (41.8)
4	104	709	64	154	1031 (15.6)
5	49	294	22	40	405 (6.1)
6	208	791	123	122	1244 (18.9)
Totals	936	4431	588	633	6588 (100)

menstrual bleeding (9% spotting and 5% BTB), and 35% reported dysmenorrhea before treatment.

At the time of enrollment into the study, 32% of the patients had already given birth; of these women, 88% had one or two children. Miscarriages and abortions had been experienced by 11% of the patients; of these women, 96% had had one or two such experiences. When questioned about their use of contraceptives, 54% had not used contraceptives previously, and 46% had used oral contraceptives. Triphasic formulations were the most common preparations used. Patients were directly switched over to the new oral contraceptive without a washout period.

Gynecologic or other concomitant illnesses were documented among 4.1% (2473) of the 59,701 patients. The most frequently reported disorders were gynecologic, reported by 1285 patients, and metabolic or endocrine, reported by 718 patients. Infections of the cervix were the most frequently reported gynecologic disorder (17%), followed by those of the breast (8%). Disorders of the thyroid gland were reported by 669 patients. Of the subjects enrolled, 1490 patients received concomitant therapy; thyroid medications were the most frequently used (by 923 patients). The high number of patients taking thyroid medications can be explained by the fact that iodine supplements are required in some parts of Germany and were evidently considered thyroid medication.

Efficacy. Efficacy was evaluated over 342,348 cycles. Pregnancies occurred in 71 women during the treatment period. Thus the use-efficacy Pearl index was 0.25 pregnancies per 100 woman-years; the 95% confidence interval was 0.19 to 0.31.

Tolerability. In all measures of tolerability, only the 42,022 patients who completed six cycles of NGM/EE were included.

Clinical variables. NGM/EE resulted in no significant changes in body weight, blood pressure, or pulse rate after six cycles of treatment. Mean body weight increased 0.6% over initial values. Mean systolic and diastolic blood pressures increased 0.5% and 1.3%, respectively, and mean pulse rate decreased 0.7% over the initial values.

Menstrual cycles. NGM/EE resulted in excellent cycle control, as demonstrated by the low incidence of BTB, intermenstrual spotting, and amenorrhea. The percentage of patients reporting BTB decreased from 4.5% before therapy to 3% after six cycles of NGM/EE treatment. Ninety-four percent of the patients reported no BTB either before the study or during cycle 6 of therapy. In 3% of the patients BTB was no longer present compared with before therapy. Only 2% reported a first episode of BTB, and 1% reported BTB before therapy and in cycle 6.

Similarly, the percentage of patients experiencing intermenstrual spotting decreased from 9% before the study to 4% after six cycles of NGM/EE treatment. Eighty-eight percent of subjects reported no spotting either before entry or during cycle 6 of therapy. Of the remaining 12%, 8% reported discontinuation of spotting after six cycles of NGM/EE, 3% who had not experienced spotting before they entered the study reported it during cycle 6, and 1% reported spotting both before therapy and in cycle 6.

Amenorrhea (no bleeding in a given cycle) occurred in only 1.4% of the women during cycle 6.

The length of cycle 6 was unaffected by NGM/EE in 62% of the patients, whereas it was shortened in 27% and lengthened in 11% compared with baseline values. The duration of bleeding in cycle 6 decreased or remained the same in 91% of patients (53% and 38%, respectively) and increased in only 9% of patients. Also, the severity of bleeding remained unchanged or was ameliorated in most patients in treatment cycle 6. Whereas 96% of patients experienced no change (64%) or a decrease in severity (32%), only 4% reported an increase compared with baseline values.

NGM/EE demonstrated no adverse effect on the reproductive tract during this study. Gynecologic disease was identified in 0.5% of the women at the beginning of the study and in 0.4% at the end of cycle 6.

Laboratory values. Total serum cholesterol, triglyceride, and blood glucose levels were evaluated in 7% of the study population before the study and after the sixth cycle of NGM/EE treatment. Cholesterol and triglyceride levels were assessed enzymatically. The number of patients with serum cholesterol, triglyceride, and blood glucose levels within normal limits at entry remained virtually unchanged during treatment. Of the 2197 patients who entered the study with total choles-

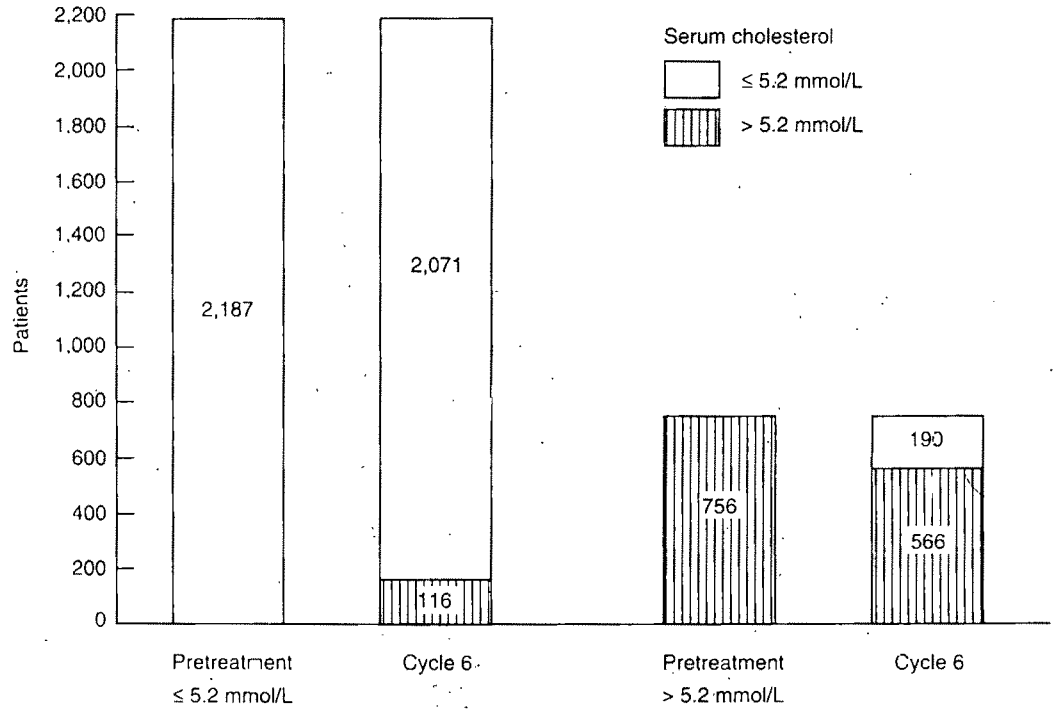

Fig. 1. Numbers of patients with serum cholesterol levels ≤5.2 and >5.2 mmol/L before and after six cycles of treatment.

terol levels in the low or normal range (<5.2 mmol/L), 95% still had low or normal levels after six cycles of NGM/EE, and 5% had increased levels (Fig. 1). Of 756 patients who entered the study with elevated cholesterol levels (≥5.2 mmol/L), 75% had levels remaining above 5.2 mmol/L, and the remaining 25% had normal or low cholesterol levels (<5.2 mmol/L) after six cycles of NGM/EE.

Similar patterns were observed for serum triglyceride levels (Fig. 2). Of the 2075 patients who entered the study with low or normal triglyceride levels (<1.7 mmol/L), 96% still had low or normal levels after six cycles of NGM/EE. On the other hand, of the 500 patients who entered the study with high triglyceride levels (≥1.7 mmol/L), 72% still had high levels, and 28% had normal levels of triglycerides after six cycles of NGM/EE.

Blood glucose levels appeared to be normalized by NGM/EE treatment (Fig. 3). Of the 2738 patients entering the study with low or normal fasting serum glucose levels (<6.4 mmol/L), 93% still had normal levels after six cycles of NGM/EE. Similarly, of 139 patients with initially high blood glucose levels (≥6.4 mmol/L), 48% had normal levels at the end of the study.

Adverse effects. The presence of acne, nausea, headaches, and breast tension (tightness in the breasts) was reported by each patient on her study calendar. The effect of NGM/EE on these side effects was evaluated by comparing the percentage of patients experiencing these symptoms at the pretherapy office visit with the percentage recording them after six cycles of treatment. Information obtained from the personal histories of 41,208 patients indicated that 35,556 (70%) never had acne either at any time before the NGM/EE study or during it. The incidence of acne was reduced from 12% during the pretherapy cycle to 9% after the six cycles of treatment. At the end of the sixth cycle of treatment, 8% of patients described their acne as persisting since before therapy, whereas 5% reported that it was no longer present. Only 1% of the patients who did not report acne before the study experienced it during the sixth cycle.

The incidence of headache also decreased during the study. Headache, which occurred in 13% of women before NGM/EE therapy, was reported by only 5% of subjects after six cycles of treatment. Headaches experienced before the study improved in 9% of women, and only 2% of subjects reported worsening of their headaches during cycle 6 of the study.

Nausea decreased from a pretreatment incidence of 6% to 4% during the sixth cycle of treatment. Although 5% of subjects reported that nausea was no longer present, 1% reported it as unchanged, and 1% experienced nausea for the first time during the sixth cycle.

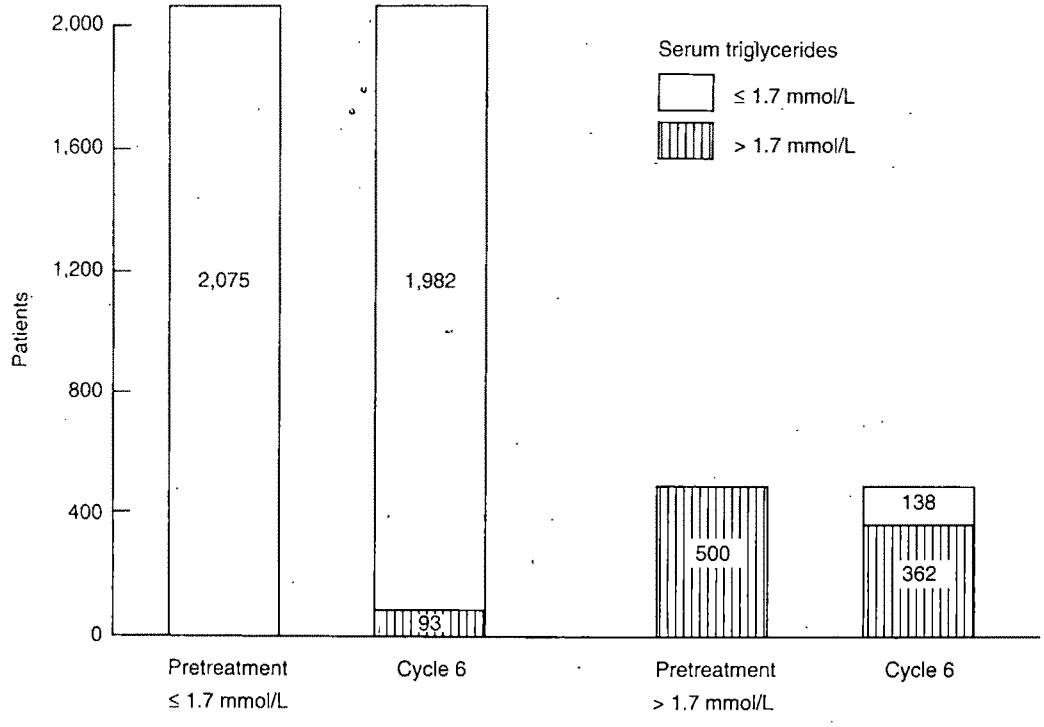

Fig. 2. Number of patients with serum triglyceride levels ≤1.7 and >1.7 mmol/L before and after six cycles of treatment.

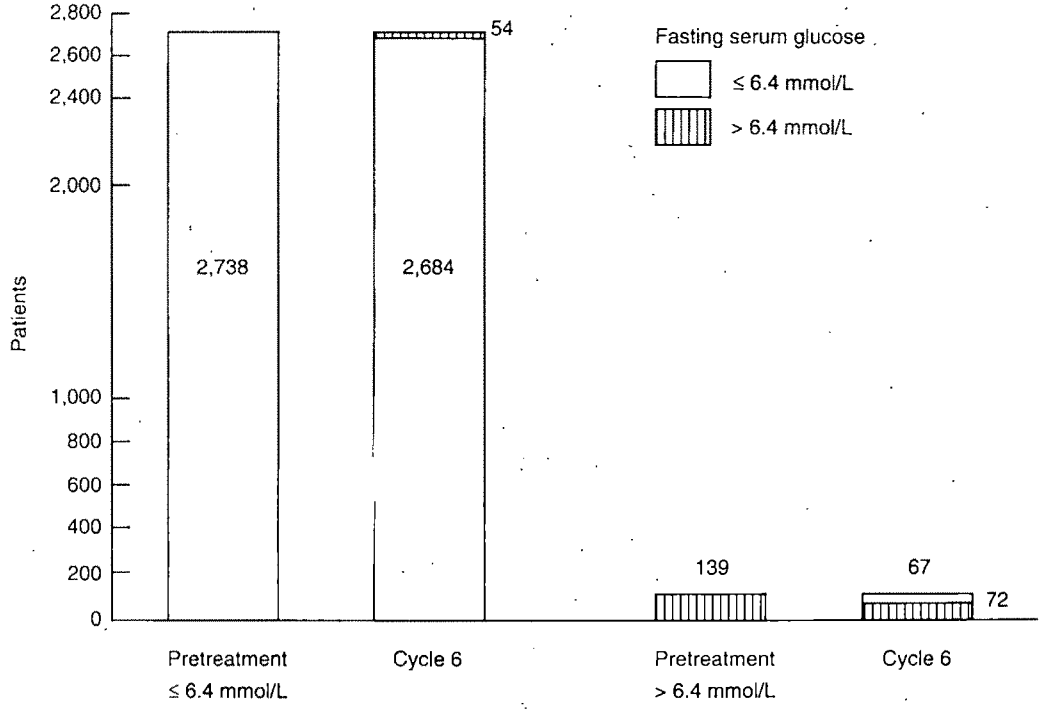

Fig. 3. Number of patients with fasting serum glucose levels ≤6.4 and ≥6.4 mmol/L before and after six cycles of treatment.

Breast tension (tightness in the breasts) was reported by 12% of subjects before they entered the study. At the end of the study, 4% of subjects no longer reported this side effect. However, 9% of patients reported breast tension as a new side effect after six cycles of NGM/EE.

Comment

The results of the present study, in which 59,701 women received NGM/EE for up to six cycles, for a total of 342,438 menstrual cycles, support those of previously reported multicenter trials, as reviewed by Corson[6] and Becker.[9] The use-efficacy Pearl index of 0.25 reported in the current study is similar to the Pearl index of 0 in a 12-month European multicenter open study of 147 women[10] and 0.64 in a 24-month U.S. comparative study of 1473 women (compared with a Pearl index of 0.62 for norgestrel).[6]

The adverse effects observed in the current study are also similar to those noted in earlier trials. In the 12-month open clinical trial (Cilag International Medical Documentation, Medoc-Report NRG 08238, 1989), only 16 adverse effects were reported by 11 patients. In that study NGM/EE had no effect on mean body weight or blood pressure. The mean duration and intensity of menstrual flow decreased during therapy. As expected, BTB and spotting are elevated (3% and 13% of patients, respectively) during the first cycle but returned to baseline levels by cycle 3/4, and amenorrhea never occurred.[10]

Other studies confirm the safety and efficacy of NGM/EE. A small study (Cilag International Medical Documentation, Medoc-Report NRG 05301, 1985) (19 patients) conducted in Germany demonstrated that NGM/EE resulted in no relevant alterations in the coagulation system after the six cycles of treatment. Another study (Cilag International Medical Documentation. Medoc-Report NRG 05288, 1985) (21 subjects; six cycles) demonstrated that NGM/EE had very low androgenic activity, as determined by high levels of sex hormone–binding globulin and low levels of free testosterone. In the same study levels of follicle-stimulating hormone, luteinizing hormone, estradiol, progesterone, and prolactin confirmed the contraceptive efficacy of NGM/EE. Furthermore, no clinically significant changes in fasting blood glucose or basal insulin levels were reported during this six-cycle study. Serum cholesterol and triglyceride levels, which were reduced in cycle 3, returned to baseline levels in cycle 6. Low-density lipoprotein cholesterol levels decreased in both cycles 3 and 6, high-density lipoprotein cholesterol levels increased during NGM/EE treatment.

In the current study, reductions in cycle length and duration of bleeding of 4% and 16%, respectively, were noted; 32% of the women experienced reductions in the intensity of bleeding. Similarly, spotting and BTB decreased over time, with 97% of women reporting an absence of irregular bleeding by the end of cycle 6. Weight, blood pressure, and pulse were minimally affected. The percentage of women who experienced acne, nausea, or headache at the end of six cycles of treatment was lower than the percentage with these symptoms before treatment with NGM/EE.

In general, for patients entering the study with normal levels of total serum cholesterol, serum triglycerides, and blood glucose, these levels were still within the normal range after six cycles of NGM/EE treatment. Of those patients entering the study with high cholesterol and serum triglyceride values, 25% and 28%, respectively, had normal levels after six cycles of NGM/EE treatment. In 50% of patients entering the study with high blood glucose levels, these levels were normal after six cycles of NGM/EE. Thus NGM/EE had minimal effects on total serum cholesterol, serum triglyceride, and blood glucose levels. These data are consistent with the more rigorous evaluations of these metabolic effects obtained in earlier trials.[6, 9]

To date all evidence indicates that NGM/EE is an effective oral contraceptive with a favorable profile for safety and patient tolerance, characterized by neutral or beneficial effects on metabolic functions and a low frequency of minor adverse effects.

Norgestimate: A clinical overview of a new progestin

Jacques Bringer, MD
Montpellier, France

The efficacy and safety of a new monophasic oral contraceptive, norgestimate/ethinyl estradiol, containing the third-generation progestin, norgestimate (250 μg), and ethinyl estradiol (35 μg), are reviewed. Norgestimate/ethinyl estradiol demonstrates excellent contraceptive efficacy, with a Pearl index of 0.25. Cycle control is reliable, with a low incidence of breakthrough bleeding and spotting. Because of the minimal androgenicity of norgestimate, norgestimate/ethinyl estradiol has a low impact on carbohydrate and lipid metabolism. It neither reduces the vasodilatory and antiaggregatory prostacyclin nor increases its endogenous antagonist, thromboxane. Norgestimate/ethinyl estradiol has no significant effect on blood coagulation factors. All these characteristics suggest that norgestimate/ethinyl estradiol may be associated with a lower risk of cardiovascular disease than other oral contraceptives currently available. Epidemiologic data, however, are not available, and physicians should be reluctant to prescribe it or any oral contraceptive to patients who have a history of vascular or thrombotic disorders. (Am J Obstet Gynecol 1992;166:1969-77.)

Key words: Progestins, prostacyclin, cardiovascular disease

Although all oral contraceptives are highly effective in preventing pregnancy, serious questions remain concerning their effect on cardiovascular disease, which is the leading cause of death in women in the United States.[1] Oral contraceptives have been found to induce changes in carbohydrate and lipoprotein metabolism that are similar to those associated with an increased risk of cardiovascular disease, primarily myocardial infarction and stroke. These changes include increases in insulin resistance and low-density lipoprotein (LDL) cholesterol, the most atherogenic of plasma proteins, as well as a decrease in serum high-density lipoprotein (HDL) cholesterol.[2-5] Many investigators have suggested that the negative impact of oral contraceptives on carbohydrate and lipid metabolism plays a major role in increasing the risk of cardiovascular disease by means of atherosclerosis.[6,7] This role is now being challenged, however, because the cause of myocardial infarction among women who use oral contraceptives has been determined to be thrombotic rather than atherosclerotic, and myocardial infarction occurs primarily in women older than 35 years of age who smoke cigarettes.[8-10] Thus a more rational explanation of the increased risk of cardiovascular disease may be that oral contraceptives induce a reduction in vasodilatory and antiaggregatory prostacyclin or an increase in its endogenous antagonist, thromboxane (TXA_2).[11]

Although epidemiologic studies indicate that myocardial infarction is extremely rare in nonsmoking oral contraceptive users, the evidence suggests there is a synergistic effect of contraceptive steroids and smoking on both the risk of myocardial infarction[10] and the inhibition of prostacyclin.[11] This hypothesis does not eliminate the important contribution of lipid alteration, however, because a reduction in HDL decreases prostacyclin synthesis in vitro[12,13] and urinary excretion of the metabolites of prostacyclin directly correlates with serum HDL_2 cholesterol levels.[14] Although it is known that decreased levels of HDL and particularly its subfraction HDL_2 are associated with the risk of coronary heart disease in the general population,[15] this relationship remains to be established in women who use oral contraceptives. However, considering the prevalence of vascular risk factors in women older than 30 years of age (Table I), it is only prudent to strive to maintain a normal blood lipid profile.[16,17]

British,[18-20] Swedish,[21] and U.S.[22,23] studies have suggested that the incidence of venous thromboembolism decreased when the estrogen dose in oral contraceptives was reduced. Although one case-control study[24] was unable to confirm these results, this may have been the result of an insufficient population base.[25] Another explanation for the reduced incidence of thromboembolic disorders in contraceptive users during the past 30 years may be that oral contraceptives have been withheld from women with a history of thromboembolism and in women scheduled for surgery.

Changes in blood coagulation factors have also been studied as a possible explanation for the increased risk of thrombosis and myocardial infarction among women who use oral contraceptives. Oral contraceptives are contraindicated for women with congenital errors of coagulation. Oral contraceptives have been shown to increase various clotting factors (II, VII, VIII, IX, X, and XII) and decrease antithrombin III,[26,27] although

Table I. Prevalence of cardiovascular risk factors among women aged 30 to 39 years*

Risk factor	*% of women*
Total cholesterol level >6.22 mmol/L	6.4
LDL level >4.14 mmol/L	7.0
HDL level <0.91 mmol/L	5.0
Hypertension	0.5
Obesity (metropolitan relative weight >130 lb)	13.6
Diabetes	0.5
Smokes >10 cigarettes/day	27.2
Parental history of coronary disease before 55 yr of age	32.3
Coronary heart disease	0.5

*Data from Wilson PWF, et al. JAMA 1989;262:41-4.

the magnitude of change in the activity of coagulation factors has not demonstrated any degree of reliability in predicting an individual's risk of thromboembolism. One study[28] suggests that oral contraceptives enhance the formation and resolution of fibrin and leave the hemostatic balance between coagulation and fibrinolysis unaltered. In another study,[29] oral contraceptives enhanced fibrinolytic activity in premenopausal nonsmoking women but not in young smokers.

Carbohydrate metabolism also can be affected by oral contraceptives. There is evidence that androgenic progestins, especially at higher dosages, can cause insulin resistance, increase plasma glucose and insulin levels, and impair glucose tolerance, although these effects rarely result in overt diabetes.[2] Therefore oral contraceptives have been contraindicated for women at risk for diabetes, such as former gestational diabetic patients.

As epidemiologic and clinical data revealed the long-term risks of oral contraceptives, the goal of contraceptive research has been directed toward developing formulations that reduce these risks while retaining optimal contraceptive efficacy and acceptable cycle control. The daily dose of the estrogen component (ethinyl estradiol) has already been decreased to the lowest level that prevents breakthrough bleeding. Now the impact of the progestational component on lipid and carbohydrate metabolism as well as on hemostasis should be minimized to increase the safety of the product. Toward this goal, three new progestins—desogestrel, gestodene, and norgestimate—have been developed for use in oral contraceptives, which are likely to be available in the United States in the early 1990s. These steroids, which represent a new generation of progestins, have lower androgenicity than their predecessors and therefore have different clinical characteristics.[30]

Results of clinical studies of a monophasic oral contraceptive (norgestimate/ethinyl estradiol) that contains norgestimate (250 μg) and ethinyl estradiol (35 μg) demonstrate how one of these progestins has achieved the goal of promoting a more positive lipid profile, has a beneficial influence on prostacyclin metabolism, and has a negligible effect on coagulation factors and carbohydrate metabolism without sacrificing efficacy of patient acceptability. Because of the latency and low incidence of side effects, it will be years before these clinical effects will be reflected in epidemiologic data. However, all indications are that this oral contraceptive may have fewer adverse metabolic effects than those currently available.

Structures of norgestimate and other new progestins

The three new progestins, like those preceding them, are 19-nortestosterone derivatives (Fig. 1). Desogestrel, with its C-11 methylene group, is metabolized to 3-keto desogestrel. Gestodene differs from levonorgestrel in that it has a double bond between C-15 and C-16. Norgestimate has a C-17 acetate group as well as a unique C-3 oxime group that inhibits its ability to bind to androgen receptors in target tissues, thus minimizing the androgenicity of the compound.

Pharmacology of norgestimate

Norgestimate has inherent progestational activity similar to that of progesterone itself (as shown by its strong binding affinity for progestin receptors in the rabbit uterus) (Fig. 2). However, it has minimal androgenicity. This was demonstrated by its relative lack of ability to stimulate the ventral prostate growth in rats, its weak binding affinity (only 0.013 times that of dihydrotestosterone) for rat androgen receptors (Fig. 3), and in its lack of affinity to bind to human sex hormone–binding globulin (SHBG).[31-33] After oral administration to women, norgestimate is well absorbed and extensively metabolized before elimination.[34, 35] Pharmacologic evaluation of the terminal metabolites revealed that 17-deacetyl norgestimate had a pharmacologic profile similar to that of the parent compound. In contrast, two other metabolites, 3-keto-norgestimate and levonorgestrel, were considerably more androgenic than norgestimate in these assays, which makes it unlikely that they made any significant contribution to the biologic activity of norgestimate. Furthermore, 17-deacetyl norgestimate appears rapidly in serum after oral administration. The peak concentrations of this metabolite greatly exceed those of the parent compound, which indicates a substantial conversion of norgestimate to 17-deacetyl norgestimate.[35] In vitro it was identified as the major metabolite of norgestimate in

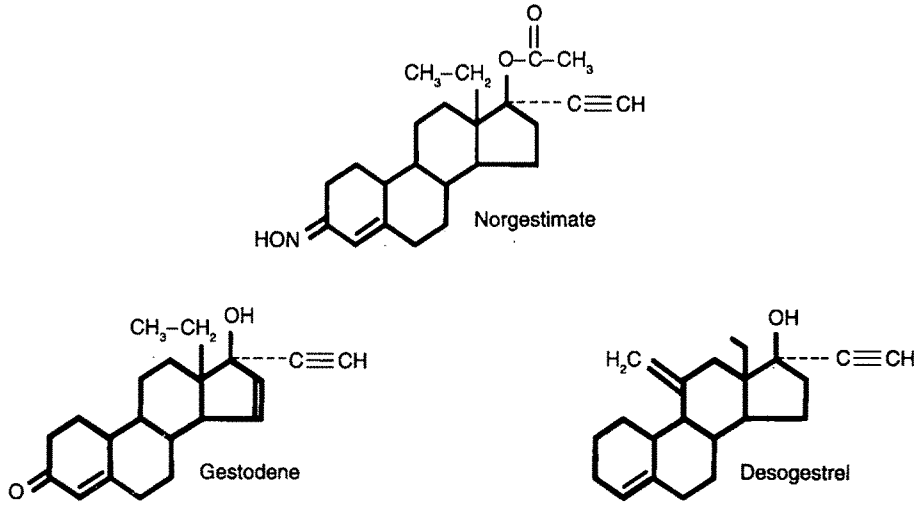

Fig. 1. The new progestins: desogestrel, gestodene, and norgestimate.

human intestinal and hepatic tissues.[36] All these data support the conclusion that 17-deacetyl norgestimate is the major metabolite of norgestimate.

Efficacy of norgestimate/ethinyl estradiol

In a 12-month multicenter German study in which 59,701 women completed 342,348 cycles of treatment, norgestimate/ethinyl estradiol (250 μg of norgestimate/35 μg of ethinyl estradiol) demonstrated excellent contraceptive efficacy, with an overall Pearl index of 0.25.[37] This is consistent with the reported rates of other combination oral contraceptives.[38] Several pharmacologic mechanisms are involved to ensure the compound's contraceptive ability. Evidence that norgestimate/ethinyl estradiol inhibits ovulation was demonstrated by its ability to abolish the preovulatory luteinizing hormone peak (Fig. 4) and to lower plasma estradiol and progesterone to levels incompatible with ovulation.[37] A separate study[39] showed that norgestimate/ethinyl estradiol alters the cervical mucus so that it is impenetrable to sperm. The results of another study[40] demonstrated that the endometrium, which showed neither proliferative nor infiltrative changes during norgestimate/ethinyl estradiol treatment, is most likely incompatible with implantation. These backup mechanisms increase the contraceptive reliability of norgestimate/ethinyl estradiol and more important offer an extra degree of protection against pregnancy in case of a missed pill..

In oral contraception, reliable cycle control is critical to compliance and therefore to the use-effectiveness of the compound. In long-term multicenter comparative clinical trials with a low-dose norgestrel-containing oral contraceptive (0.30 mg of norgestrel plus 0.03 mg of ethinyl estradiol), norgestimate/ethinyl estradiol demonstrated a similar low incidence of breakthrough bleeding and a lower incidence of amenorrheic cycles than did the norgestrel-containing compound. With norgestimate/ethinyl estradiol, clinical side effects, especially those associated with androgenicity, were infrequent, and patient discontinuation because of these side effects was minimal. Weight gain was cited by only 0.84% of subjects who took norgestimate/ethinyl estradiol (vs 1.54% of subjects taking norgestrel/ethinyl estradiol) as the reason for discontinuation, and acne was cited by another 0.84% of patients taking norgestimate/ethinyl estradiol (vs 1.20% of patients taking norgestrel/ethinyl estradiol) as the reason for discontinuation.[41]

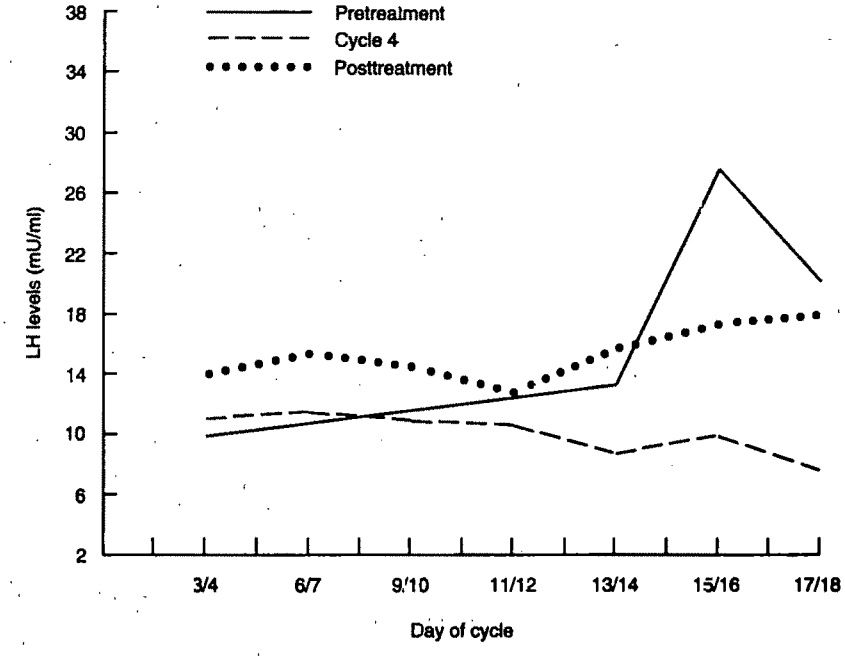

Fig. 4. The effect of norgestimate/ethinyl estradiol on luteinizing hormone *(LH)* levels.

may also cause unwanted androgenic side effects indirectly. Androgenic progestins can do this either by lowering serum levels of the carrier protein, SHBG, or by binding to it, thereby displacing testosterone and resulting in increased levels of free active testosterone (Table II).[42] Estrogens increase SHBG levels, but in women taking oral contraceptives, androgenic progestins tend to oppose the estrogen-induced increase in SHBG.[43] Thus serum SHBG levels can be used to evaluate the balance between the androgenicity of the progestational component and the estrogenic component in women taking oral contraceptives. The results could have clinical implications because decreased serum concentrations of SHBG have been associated with an increased risk of myocardial infarction in postmenopausal women, which strengthens the link between androgenicity and atherosclerosis.[44]

In one clinical study,[45] norgestimate/ethinyl estradiol nearly doubled SHBG levels from their baseline levels after three and six cycles of therapy, while at the same time there was almost a 50% decrease in free testosterone levels. In another study[41] that compared the effects of norgestimate/ethinyl estradiol with those of a norgestrel-containing oral contraceptive, after four cycles serum SHBG levels were between 68.5% and 161.2% above baseline levels in the norgestimate/ethinyl estradiol group compared with only 12.8% to 26.2% above baseline levels in the norgestrel/ethinyl

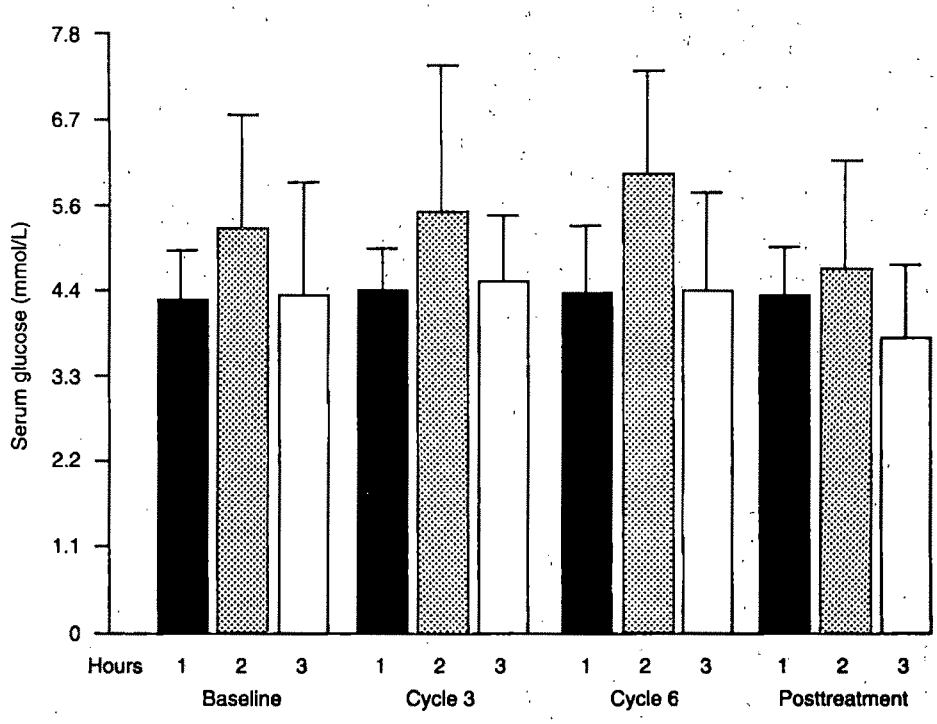

Fig. 5. The effect of norgestimate/ethinyl estradiol on serum glucose at 1, 2, and 3 hours after oral glucose load. There was basically no effect.

estradiol group. These data further confirm the minimal androgenicity of norgestimate.

Glucose tolerance

Most investigators have found that depending on the type and dose of progestin, oral contraceptives have an adverse effect on carbohydrate metabolism and increase blood glucose and plasma insulin.[2, 46-48] The clinical importance of this finding is that impaired glucose tolerance is among the main factors for the development of atherosclerosis,[49] and the impact on the carbohydrate metabolism paralleled the impact on lipid metabolism.[50] Most investigators[30, 51, 52] have found that norethindrone and the new generation progestins, gestodene and desogestrel, have a more favorable impact on carbohydrate metabolism than the more androgenic norgestrel. However, Van der Vange et al.[53] reported that the areas under the curve for both insulin and glucose were unchanged by any of the seven oral contraceptives tested, including levonorgestrel, norethindrone, desogestrel, and gestodene.

The effects of norgestimate/ethinyl estradiol on carbohydrate metabolism were evaluated in 21 women during oral glucose tolerance tests conducted in the third and sixth treatment cycles and again in the second posttreatment cycle.[37] Norgestimate/ethinyl estradiol had no effect on serum glucose levels (Fig. 5). Although insulin levels were slightly higher in the sixth treatment cycle than during pretreatment, they returned to normal range in the second posttreatment cycle. Data on the effects of norgestimate/ethinyl estradiol in gestational, insulin-dependent, and noninsulin-dependent diabetic patients are not available.

Lipoprotein metabolism

Although it is known that high serum levels of LDL cholesterol represent a major risk factor for myocardial infarction and low serum levels of HDL cholesterol are protective against myocardial infarction for women more than 30 years old in the general population,[54, 55] this relationship has not been found to also be true for young oral contraceptive users. However, because HDL increases prostacyclin synthesis in vitro[12, 13] and correlates with urinary excretion or prostacyclin metabolites,[14] it is possible that preventing a decrease in HDL levels could also reduce the thrombotic coronary risk in oral contraceptive users. Whereas the importance of maintaining a normal blood lipid profile with high levels of HDL and its subfraction is well recognized, recent evidence demonstrates that the administration of HDL fractions to rabbits inhibits not only the development and progression of fatty streaks and lipid deposition in the aortic walls in rabbits but can significantly reduce preexisting experimentally induced atherosclerotic lesions.[56]

Norgestimate/ethinyl estradiol results in significant increases in both HDL and HDL_2 levels after six cycles of treatment (Figs. 6 and 7)[37] and significant increases

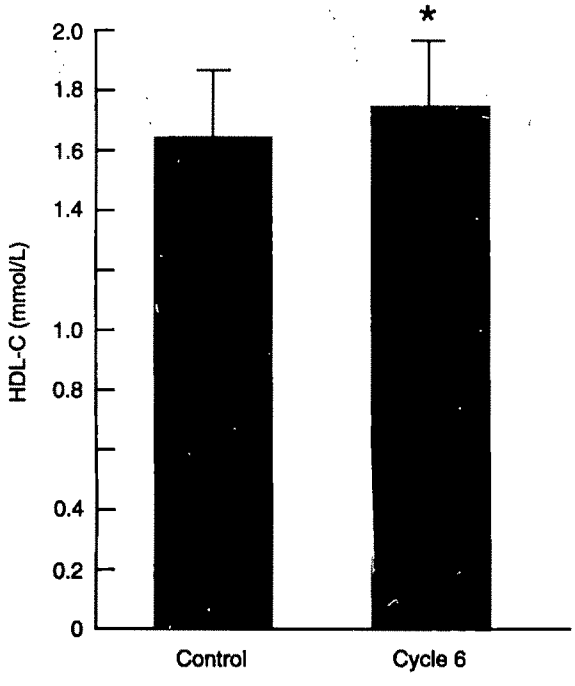

Fig. 6. The effect of norgestimate/ethinyl estradiol on total HDL cholesterol *(HDL-C)*. HDL-C levels increased significantly after six cycles of treatment ($*p < 0.01$).

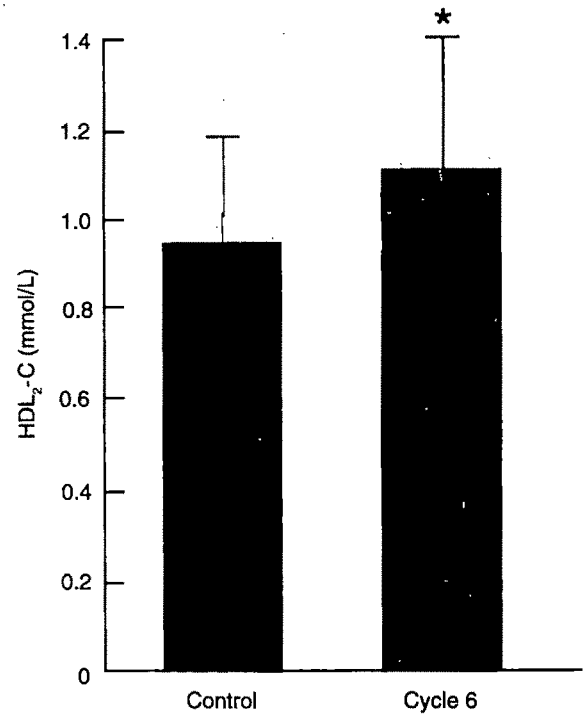

Fig. 7. The influence of norgestimate/ethinyl estradiol on HDL_2 cholesterol *(HDL_2-C)*. There was a significant increase in HDL_2-C levels after six treatment cycles ($*p < 0.01$).

Table II. Characteristics and potential clinical effects of androgenic progestins

Characteristics
↑ Binding to androgenic receptors
↑ Binding to SHBG

↓ Serum HDL levels
↑ Serum LDL levels
↓ Serum triglycerides
↑ Insulin resistance
↑ Body weight
↑ Cardiovascular risk

in HDL in treatment cycles 3, 6, 12, and 24 without a significant change in LDL at 12 and 24 months.[41] As expected with the progestins, which have low androgenic activity in combination with estrogen,[57] norgestimate/ethinyl estradiol results in a moderate increase in triglyceride levels.[37] However, data from the Framingham Study suggest that elevated triglyceride levels constitute a cardiovascular risk factor in women only when associated with low HDL levels.[58]

There is a risk in uncritically accepting and interpreting the results of any single study because of the numerous sources of variability in each: age of subjects, smoking, exercise, diet, weight, pretreatment lipid levels, time of day the samples were drawn, and the methodology of analysis of the samples.[59] For example, of 25 published studies of oral contraceptives containing 30 μg of ethinyl estradiol and 150 μg of levonorgestrel, 12 studies reported that the LDL concentration was decreased and 13 reported it was unchanged.[60] However, Chapdelaine et al.[41] have shown that after 24 cycles of norgestimate/ethinyl estradiol (0.25 mg/0.035 mg), mean serum HDL levels were significantly (0.12 mmol/L) above baseline levels, whereas after 24 cycles of norgestrel/ethinyl estradiol (0.30 mg/0.03 mg), HDL levels were significantly (0.07 mmol/L) below baseline levels. These data appear to be reliable, especially in view of the cumulative data showing that norgestrel has significantly more androgenic activity than does norgestimate.

Effects of norgestimate/ethinyl estradiol on prostacyclins

Vasodilatory prostacyclin inhibition or increased vasoconstrictory TXA_2 activity may be important mechanisms for the increased cardiovascular risk among women who take oral contraceptives and smoke cigarettes.[10, 11, 14] There is evidence that smoking decreases prostacyclin formation and increases platelet aggregation in women who use oral contraception.[11]

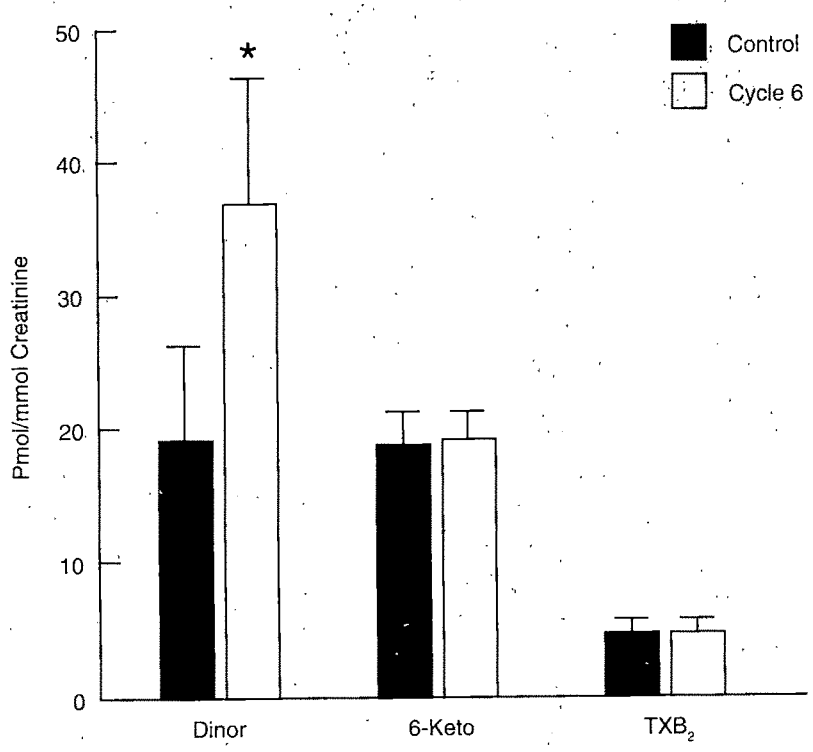

Fig. 8. The effect of NGM/EE on urinary dinor excretion, 6-keto metabolite of prostacyclin, and TXB_2. (*$p < 0.01$).

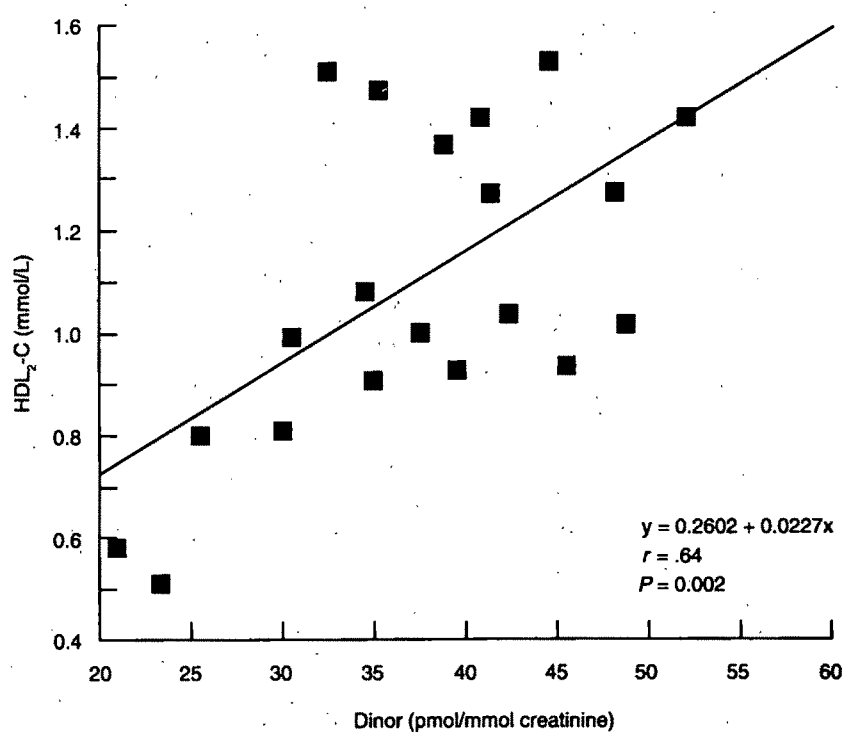

Fig. 9. The relationship of HDL_2 cholesterol *(HDL_2-C)* to urinary excretion of the dinor metabolite of prostacyclin after norgestimate/ethinyl estradiol. (Source of data: Foidart.[61]).

Foidart's study[61] reveals that norgestimate/ethinyl estradiol has no influence on either the 6-keto metabolite of prostacyclin or thromboxane B_2 (TXB_2) metabolite of TXA_2 after six cycles of therapy. On the other hand, urinary dinor excretion, probably the most sensitive index in vivo of prostacyclin, increased significantly (Fig. 8) and correlated with total serum HDL_2 (Fig. 9). These findings suggest that the physiologic regulating system of prostacyclin by HDL is not affected by norgestimate/ethinyl estradiol. Ylikorkala et al.[14] have shown that desogestrel plus ethinyl estradiol has similar beneficial effects: it increased urinary dinor excretion but had no effect on 6-keto prostacyclin or TXB_2 excretion. However, although desogestrel plus ethinyl estradiol increased HDL and HDL_2, there was no correlation between urinary dinor excretion and HDL_2 concentration. Theoretically these increases in prostacyclin metabolites and HDL might decrease the risk of occlusive-thrombotic vascular disorders.

Blood coagulation factors

The association of hypercoagulability with oral contraceptive use is well documented, and these changes are likely to have a role in the risk of thromboembolism and myocardial infarction among women who use oral contraceptives, although long-term epidemiologic studies are needed to show their clinical significance as reliable indicators of risk.[25]

A study conducted in Germany with 19 healthy volunteers demonstrated that norgestimate/ethinyl estradiol produced no changes in fibrinopeptide A (the most sensitive marker of activation of the coagulation system), anticoagulation factors antithrombin III and protein C, or coagulation-promoting factors fibrinogen, factor VII, and the components of factor VIII.[37]

Summary

The effects of norgestimate/ethinyl estradiol on carbohydrate metabolism, lipid metabolism, prostacyclin synthesis, and blood coagulation have been presented in relation to the risk of cardiovascular disease, which is the leading cause of death in women in the United States. Because norgestimate has minimal androgenic activity, norgestimate/ethinyl estradiol has a low impact on these systems. The relative absence of effect of these parameters suggests that norgestimate/ethinyl estradiol may have the advantage of a greater degree of safety over older oral contraceptive formulations. However, long-term epidemiologic studies are needed to determine if the above clinical results will be effective in decreasing the risk of cardiovascular disease associated with older oral contraceptive formulations.

Discussion I

Chairman Mishell. Dr. Grimes, can you present evidence to support your view that myocardial infarction in women who use oral contraceptives is caused by thrombosis and not atherosclerosis? Will you also discuss why this risk is reduced with moderate- and low-dose oral contraceptive formulations?

Dr. Grimes. The Engel et al. study[1] from Europe probably provides the most compelling evidence. The investigators found that, in the case of women who had been using oral contraceptives and died of myocardial infarction, thrombosis and not atherosclerosis was usually the cause. In addition, evidence shows that women who formerly used oral contraceptives are not at increased risk for myocardial infarction after they have stopped using the oral contraceptives, and no dose-response effect is found.

We do not see this effect with the low-dose pills, as shown in studies by Rosenberg et al.,[2] Stampfer et al.,[3] and others. I believe the evidence is reassuring.

Chairman Mishell. Dr. Grimes, the current trend is to continue to prescribe oral contraceptives for women who are older than 35 years of age. How will this prolonged use of oral contraceptives affect a woman's risk of developing breast cancer in later years?

Dr. Grimes. Again, I believe compelling evidence shows that in general the use of oral contraceptives has no effect on the incidence of breast cancer. However, questions remain about long-term use of oral contraceptives by young women. Only continued studies over the next 15 to 20 years will determine whether the risk of breast cancer is related to the use of low-dose oral contraceptives.

Chairman Mishell. Dr. Grimes, you also showed that high dose oral contraceptives decrease the risk of developing ovarian cysts and endometrial and ovarian cancers. Are the benefits still present with lower-dose agents?

Dr. Grimes. I believe the literature concerning oral contraceptive safety should be rewritten for today's low-dose pills. Two studies that were sufficiently large, however, have looked at low-dose formulations. These are the Cancer and Steroid Hormone Study of ovarian cancer and endometrial cancer.[4,5] These studies reported the same protective effect even with low-dose pills.

Chairman Mishell. How long after menopause should women take oral contraceptives for menopausal symptoms?

Dr. Grimes. In general, my preference is to prescribe hormone replacement therapy, which has a lower dose of steroids than contemporary oral contraceptives.

Chairman Mishell. It is not a lower dose—just a lowered biologic activity—because the steroids are less potent.

Dr. Grimes. Yes.

Chairman Mishell. How long must a woman wait after she stops smoking until she can be considered a safe candidate for oral contraceptive use?

We have data on prostacycline and thromboxane levels; women who smoke and take the pill have a relative excess of thromboxane. After they stop smoking the excess thromboxane disappears, and there is really no evidence of increased cardiovascular risk in women taking oral contraceptives who have stopped smoking. I believe that once a woman stops smoking she is not at increased risk for vascular disease.

Mr. Godsland, we know that estrogen increases the blood supply to the heart and that this effect is partially responsible for the cardioprotective effect of estrogen. Is anything known about the effect of oral contraceptives on coronary artery blood flow?

Mr. Godsland. I know of no evidence regarding the effect of oral contraceptives on coronary artery blood flow. However, to the extent that improvement in coronary artery blood flow appears to be an estrogenic effect, those oral contraceptive combinations that are less progesterone dominant might be expected to have a positive effect on the coronary artery blood flow.

Chairman Mishell. Mr. Godsland, you reported a good effect on high-density lipoprotein and low-density lipoprotein cholesterol with the low-dose estrogen and low-dose progestin pill. Can these new combination pills be used by women who already have hyperlipidemia or hypertriglyceridemia and low high-density lipoprotein levels?

Mr. Godsland. Certainly the newer progestins, in which the effects of estrogen are more apparent, are suitable for a woman who has, for example, a high low-density lipoprotein cholesterol concentration. I think we should be more careful with the more severe lipid abnormalities, such as hypertriglyceridemia. The physician should proceed with caution when the patient has a severe abnormality and should perform serial measurements of lipoproteins during oral contraceptive use. However, if a woman is moderately overweight or has low high-density lipoprotein cholesterol levels, I would be fairly confident about prescribing the new combination pills.

6/0/37510

Chairman Mishell. Do you believe that being overweight by itself is a contraindication for oral contraceptive use?

Mr. Godsland. I would make a distinction between being moderately overweight—between 120% and 135% ideal body weight—and severe obesity. Although I believe that severely obese patients should be carefully monitored, I am not sure an absolute contraindication exists. We need more information.

Chairman Mishell. Dr. Runnebaum, is it safe to prescribe a product with norgestimate for women who have lipid abnormalities?

Dr. Runnebaum. The information we presented in our paper were cumulative data about changes in lipid levels in women who receive the low-dose norgestimate oral contraceptive. We ae now performing further analyses of the pretreatment incidence of different types of lipid disorders, such as hypercholesterolemia, and are assessing the individual lipid changes during oral contraceptive use.

Chairman Mishell. Dr. Bringer, what do you think?

Dr. Bringer. In my opinion the epidemiologic data are insufficient to answer this question. We must be careful when we make individualized decisions and recommendations, because even with the new compound, we have no data at this time on risk factors.

Chairman Mishell. Can a woman undergo elective surgery if she is taking oral contraceptives? If the answer is no, how many days before surgery is it necessary to withdraw the oral contraceptives?

Dr. Grimes. The current recommendation that women discontinue taking oral contraceptives about 30 days before elective major surgery stems from case-control studies performed with older, high-dose pills in the early 1970s in the United Kingdom and the United States. In those studies a three- to sixfold increase in the risk of postoperative thrombosis was seen if a woman had been taking the pill.

In general physicians have not recommended that patients discontinue oral contraceptive use before minor procedures, such as laparoscopy. To what extent those data are relevant to today's low-dose pills remains to be seen.

Chairman Mishell. Dr. Grimes, which factor do you believe has contributed the most to reducing the side effects of oral contraceptives, particularly ischemic heart disease and strokes: the reduced dosages of steroids, the better selection of users (in other words, excluding smokers)?

Dr. Grimes. I am not certain that important question has an answer. We cannot disentangle which factor caused the decline.

Chairman Mishell. Why are products that contain the new progestins not marketed in the United States when they have been marketed in Europe for at least 5 years?

Dr. Grimes. That is an imponderable question. We must deal with regulatory agencies in the United States.

Chairman Mishell. I believe that these products will be marketed in the United States within the next few months. At least, we are hopeful they will be available because of their demonstrated value, as shown in the studies presented at this symposium.

Introduction to steroids in the menopause

Göran Samsioe, MD, PhD*
Göteborg, Sweden

Menopausal symptoms and signs associated with the reduction of ovarian function include an increased incidence of cardiovascular disease and loss of bone mass as well as less serious but more uncomfortable symptoms such as vasomotor flushes and atrophy of the vaginal wall. Although unopposed estrogen effectively reverses these and other menopausal symptoms, it is well established that without the addition of progestin there is an unacceptably high risk of developing hyperplasia or cancer of the endometrium. Depending on the type and dose of progestin added, however, this addition may reverse estrogen's beneficial cardiovascular effects and produce unwanted side effects. Lower doses and newer progestins, such as norgestimate, gestodene, and desogestrel, have demonstrated a decreased potential to reverse the positive cardiovascular effects of estrogen while still eradicating persisting or de novo endometrial hyperplasia. (AM J OBSTET GYNECOL 1992;166:1980-5.)

Key words: Progestin, hormone replacement therapy, menopause

In addition to mitigating vasomotor symptoms and alleviating urogenitary discomforts, estrogen replacement therapy favorably influences the incidence of fractures and cardiovascular disease. The symptomatic relief of estrogen deficiency symptoms has long been recognized. Despite the fact that 80% of women at some time experience symptoms of estrogen deficiency, only a few receive replacement therapy. Because of various, mainly nonmedical factors, the percentage of women in industrialized countries who use hormone replacement therapy varies from 4% to 40%. The duration of therapy is usually short (6 months to 3 years) in most countries.

Including preventive measures as an indication for hormone replacement therapy should lead to extended treatment periods provided that safety is maintained. Available cost-benefit analyses agree with the assumption that lives could be saved if hormone replacement therapy was used more extensively. In addition, results from several studies[1, 2] show that quality of life is greatly improved in women using hormone replacement therapy compared with age-matched control subjects. Hence a growing body of evidence suggests that hormone replacement therapy increases not only quality but also quantity of lives. Yet hormone replacement therapy remains little used. Excluding the positive cost-benefit analyses, several other factors may lead to a rapid increase in the use of hormone replacement therapy within the next few years.

Factors leading to increased use of hormone replacement therapy

The number of women reaching the climacteric is rapidly growing as those women born after World War II now approach menopause. Generally this generation is better educated, partly as a result of input from the mass media such as television and radio. With the introduction of oral contraceptives in the early 1960s, it was suddenly possible to avoid an undesired pregnancy. With this accomplishment, it is inconceivable that this generation would accept the difficulty of menopausal symptoms. Furthermore, many of these women already have personal experience with hormonal medication such as oral contraceptives.

In Europe some women of climacteric age complain about the noninterest and unwillingness of physicians, including some gynecologists, to recommend hormone replacement therapy.[3] A recent survey among general practitioners in Norway also confirmed that younger physicians and female colleagues were more prone than older and male colleagues to discuss hormone replacement therapy with women of climacteric age. There was also a correlation between interest in hormone re-

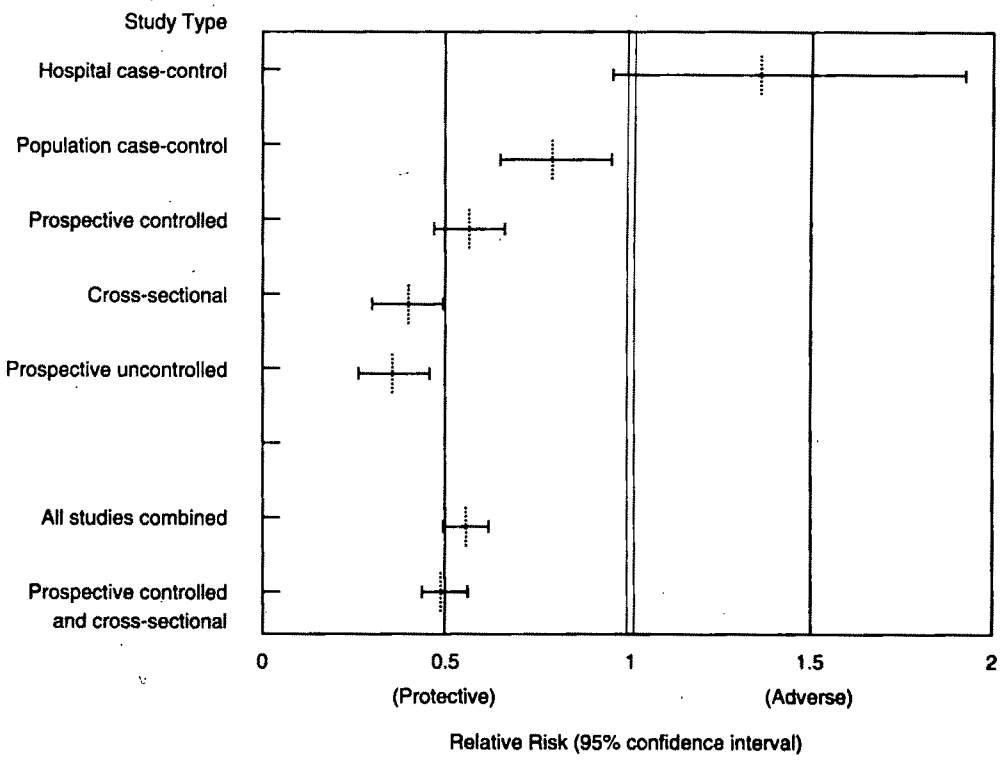

Fig. 1. Comparison of relative risks of coronary heart disease by study type among women receiving estrogen therapy. (From Stampfer MJ, Colditz GA. Prev Med 1991;20:47-63.)

placement therapy and the physician's knowledge about the pros and cons of such regimens.

Information seems to be the primary need not only to gynecologists but also to journalists and politicians as well as to women and men in general. Such information should in particular be directed to cardiologists, orthopedic surgeons, geriatricians, and general practitioners, who are consulted by a considerable part of the female population of menopausal ages. It is also important to address the issue of potential health benefits to those women who do not experience vasomotor symptoms. A more detailed outline is difficult, because it would depend on the medical infrastructure of each community.

Treatment periods may also be lengthened. The evidence suggests that estrogens and estrogen-progestin combinations prevent osteoporosis. Estrogens are mainly considered antiresorptive agents, but recent reports[4, 5] imply that estrogens could be used for the treatment of established osteoporosis, a fact that may be of great importance for future health strategies. Several consensus committees have concluded that estrogen is most effective for preventing osteoporosis during the years surrounding menopause, which in turn would lead to treatment periods of 10 to 15 years.

The cardioprotective effect of estrogens has also been documented (Fig. 1). Admittedly, results from large, multicenter, controlled clinical trials are unavailable, but observational data are impressive and consistent with the notion that estrogens reduce cardiovascular disease by 50%.[6] Most studies of estrogen replacement therapy and cardiovascular disease enroll women with no previous manifestations of arterial disease. The arteriosclerotic plaque serves as an outstanding matrix for the formation of a clot. It would therefore seem possible that estrogen use could be potentially hazardous for women with advanced arteriosclerosis, provided that estrogens promote thrombotic events. In the Leisure World Study, Henderson et al., and Paganini-Hill et al.[8] demonstrated that women with previous myocardial infarction or stroke also benefitted substantially from estrogen therapy. In fact the protective effect seemed to be the same regardless of previous history of arterial disease. Looking more specifically at this problem, Bush[9] in the Lipid Research Clinics study found that the relative risk of subsequent arterial disease in women with a past history of myocardial infarction was 0.2. Thus it seems as if those subjects who were at the highest risk had the most to gain from estrogen replacement therapy. Data from Sullivan et al.[10] comply with this notion, as angiographically documented arteriosclerosis diminished during estrogen

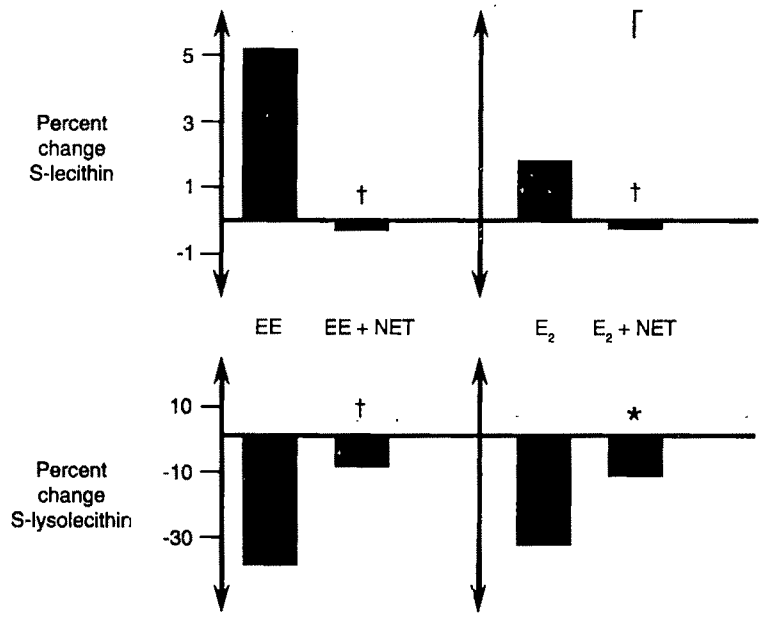

Fig. 2. Changes in lecithin and lysolecithin content of LDL during estrogen replacement therapy. *EE*, Ethinyl estradiol; *NET*, norethindrone; E_2, estradiol. $*p < 0.01$; $\dagger p < 0.001$. (Modified from Silfverstolpe G, et al. Acta Endocrinol 1981;95:527-33.)

intake. The most dramatic reduction was seen in advanced cases. If these data can be confirmed, estrogen therapy would be one of the more efficacious secondary prevention measures for women with previous myocardial infarction.

Current users of estrogen replacement therapy seem to have a far better "protection" from cardiovascular disease than do former users, who in turn are better off than nonusers.[11] These observations may imply that besides influencing atherogenesis, other mechanisms that improve cardiovascular function are also exerted by estrogens. Such mechanisms include vasodilatation and reduced vascular resistance, which in turn lead to an increase in blood flow.[12, 13]

Also of interest is the observation that lowering low-density lipoprotein (LDL) also improves rheologic properties of blood.[14] The clinical relevance of such changes are supported by the findings of enhanced blood flow to skeletal muscle and higher muscle tension of oxygen after extracorporal removal of LDL (LDL-apheresis) in patients with hypercholesterolemia.[15] Furthermore, experimental arteriosclerosis induced by high cholesterol levels is accompanied by an increase in vascular tone.[15] These findings may be related to impaired function of the endothelium-derived relaxing factor. Whether synthesis, release, or breakdown of endothelium-derived relaxing factor is affected by LDL cholesterol remains to be clarified.[16] Recent data[14] also suggest that hemodynamic changes occur before the gross appearance of an atheroma. The changes in cholesterol metabolism and the concomitant reduction in blood pressure and improvement in hemorrheology in women who use estrogen remain to be clarified.

It should be noted, however, that measuring quantitative lipid changes may not be the full answer to the lipid-arteriosclerosis relationship. It has recently been established that qualitative changes, especially in LDL, play an important role in atherogenesis. Even minimally modified LDL particles may dramatically increase their atherogenicity. Such modifications in LDL comprise above all oxidative processes. In addition to it being highly atherogenic, oxidized LDL is characterized by a low content of polyunsaturated fatty acids and lecithin and a higher content of lysolecithin in comparison with native LDL. Estrogens increase lecithin and polyunsaturated fatty acids in plasma, concomitant with a reduction of lysolecithin (Fig. 2).[17] It would seem likely that the multifactorial effects of estrogen in reducing cardiovascular disease also include the reduced formation of modified (oxidized) LDL particles.

Furthermore, dietary supplementation of n-3 fatty acids in pigs has resulted in augmented release of endothelium-derived relaxing factor from coronary artery segments as well as increased sensitivity of vascular smooth muscles to the effects of endothelium-derived relaxing factor.[18] Because estrogen-progestin combinations may influence the relative fatty acid composition,[19] other intriguing possibilities for estrogen effects may arise.

The plasma concentration of estradiol after the administration of nonoral estrogens, such as those used in the transdermal patch, is similar to that of the fol-

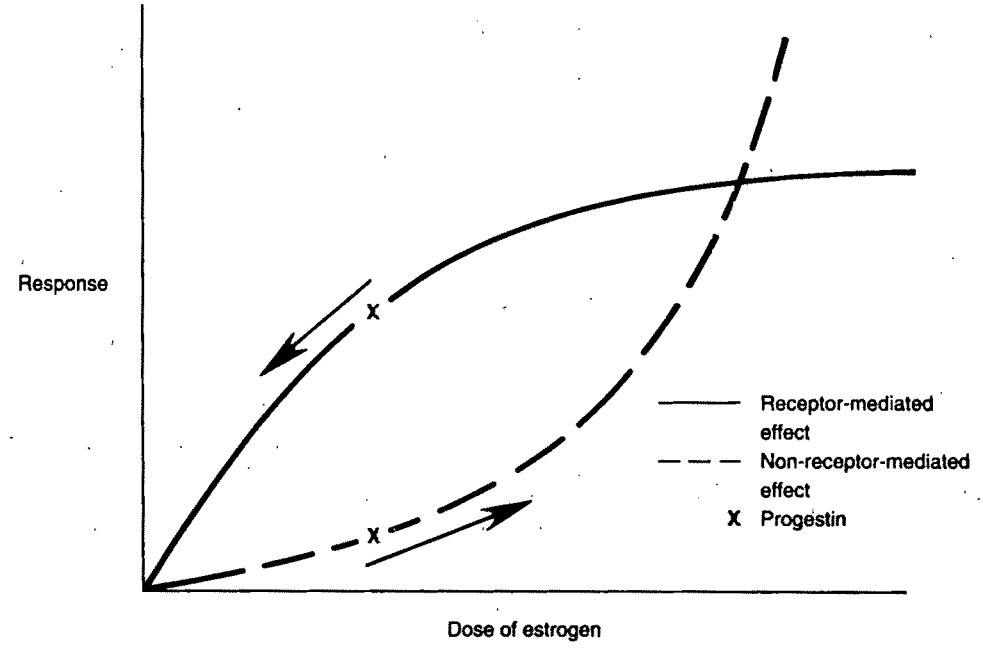

Fig. 3. Variable dose responses to estrogen and progestin.

licular phase and hence more closely resembles physiologic conditions than does oral therapy. A growing body of evidence suggests that most of the cardioprotection offered by estrogens is accomplished by direct effects on the vascular wall that comprise both biochemical (e.g., effects on LDL oxidation and endothelium-derived relaxing factor) and physiologic events. Therefore nonoral estrogen delivery systems are likely to be as beneficial as oral estrogens in relation to cardioprotection even though the plasma biochemical profile might be different. By avoiding the first passage through the liver, nonoral estrogens display less marked changes in liver-derived constituents as exemplified by factors belonging to the coagulation cascade. In addition, transdermal patches seem to lower triglyceride and LDL-cholesterol levels, thereby leaving high-density lipoprotein (HDL) levels virtually unchanged.[20, 21]

Use of progestins in estrogen replacement therapy

Whether progestins per se influence the incidence of cardiovascular disease is unknown. There is no natural situation in which progestogen is secreted without the concomitant secretion of estrogens. Our current understanding is based on reports in women who use oral contraceptives or are undergoing treatment for endometriosis or malignancies of the endometrium or breast, and results are blurred by the underlying disease. In fertile women the overall impression is that progestin administration does not increase the risk of cardiovascular disease more than depletion of ovarian function would suggest.

A decade ago data appeared in the literature indicating a metabolic difference between 17α-hydroxyprogesterone derivatives and progestogenic compounds derived from 19-nortestosterone. These data were based on studies comprising only three progestins, namely, medroxyprogesterone acetate as a member of the 17 α-hydroxyprogesterones and levonorgestrel and norethindrone as examples of 19-nortestosterones. However, more recent studies[22, 23] on other progestogenic compounds have not verified the extrapolation of the data on these three progestins to be valid for all progestins. Marked metabolic differences between progestins exist, but the reasons are more complicated than a mere dissimilarity in parent chemical structure. Earlier preparations of medroxyprogesterone acetate had a poor oral bioavailability,[24] which to some extent explains its relative inertness in previous work. By improving its absorption, medroxyprogesterone acetate now shows some of the characteristics of other progestins, for example, lowering of HDL levels.[25, 26]

In several physiologic and biochemical events, progestins counteract the effects of estrogens on insulin concentrations, triglyceride levels, and total and HDL- and LDL-cholesterol. They also produce vasoconstriction of estrogen-primed arteries. Therefore it is natural to assume that the addition of progestin might harm estrogen-induced cardioprotection. However, the scare epidemiology that exists does not support such an assumption. To date only three studies[27-29] have addressed

the problem of cardiovascular disease and combined therapy. However, all three suggest that the progestin does not negatively influence cardioprotection. The progestins involved were norethindrone,[27] medroxyprogesterone acetate,[28] and levonorgestrel.[29] These findings are further supported by experimental data[17] and animal models.[30,31] It should be stressed that in this context pharmacologically induced changes of HDL may not have the same clinical significance in relation to the risk of cardiovascular disease as HDL has in population-based samples.[32]

Although insufficient, the results of these studies render it necessary to have a revised hypothesis regarding the mechanisms by which female sex steroids influence arterial function and integrity. As seems to be the case with bone mineral metabolism, progestins apparently do not counteract the estrogen effects but could in fact show additional or even synergistic effects. A novel hypothesis on mechanisms of action by estrogens and progestins takes into account not only the classic receptor-mediated effects but also effects exerted by nongenomic (i.e., non-receptor-mediated) actions (Fig. 3).[26]

Estrogens and adverse side effects

Safety is of primary concern when dealing with preventive measures. This is further accentuated when the number of users is growing and particularly when treatment periods expand. Estrogens are known to increase the risk of endometrial cancers, a side effect that can be controlled for by adding progestin to the estrogen replacement therapy. Two major problems remain: the breast cancer issue, which will be covered elsewhere, and the bleeding problem. The longer the treatment period, the more distress a patient experiences because of vaginal bleeding, especially if the bleeding is heavy and irregular. The bleeding pattern improves if compliance can be maintained, a fact that has been underlined by the popularity of the fixed estrogen-progestin combination tablets that are available in Europe.

The introduction of continuous combined preparations offers a possibility for a number of women to receive hormone replacement therapy without bleeding and still be protected from endometrial hyperplasia and possibly endometrial cancer. With a growing understanding of the reasons for bleeding from an atrophic endometrium, continuous combined regimens could be improved.[33-35] The introduction of tibolone as treatment for climacteric symptoms is also noteworthy. This steroid combines estrogenic, progestogenic, and androgenic properties in one molecule. Its clinical performance and bone-preserving abilities are good.[36] Data on cardiovascular disease are lacking, but treated patients have lower triglyceride levels than do control subjects and no significant alterations in LDL or HDL.[38]

The benefits and risks of hormone replacement therapy: An epidemiologic overview

Susan Harlap, MB, BS
New York, New York

In postmenopausal women estrogens alone are effective in reversing vasomotor symptoms and vaginal atrophy. They also prevent the bone loss associated with osteoporosis and reduce the risk of cardiovascular disease, probably through their beneficial effects on lipid metabolism. Unopposed long-term estrogen therapy, however, increases the risk of developing endometrial hyperplasia, endometrial cancer, and possibly breast cancer as well. The risk of developing endometrial cancer can be reduced by combining a progestin with the estrogen, by controlling obesity, and by rigorous clinical screening and surveillance. The effect of progestins on the risk of developing breast cancer is still controversial. Although some progestins may reverse the cardioprotective effect of estrogens, those with minimal androgenicity appear less likely to do so. Hormone replacement therapy that combines estrogen with a progestin of minimal androgenicity is thus a rational alternative to unopposed estrogen therapy. Current epidemiologic knowledge suggests that the benefits of hormone replacement therapy, with or without any progestins, strongly outweigh the risks. (AM J OBSTET GYNECOL 1992;166:1986-92.)

Key words: Hormone replacement therapy, estrogens, progestins, cardiovascular disease, breast cancer, endometrial cancer

It has been known for many years that lack of estrogen is the cause of menopausal symptoms. In 1932 Geist and Spielman[1] first proposed that women be given estrogens to reverse these symptoms. In the 1940s a link was established between estrogen deficiency and osteoporosis,[2] and in the 1950s it was recognized that estrogen inhibited atherosclerosis.[3] A clinical trial[4] with men as subjects was performed to test the hypothesis that high doses of conjugated estrogens would prevent coronary heart disease; the trial was stopped when the men who had been treated with estrogen experienced more nonfatal myocardial infarction, pulmonary embolism, and thrombophlebitis than did the untreated men. The trial did not study the more physiologic low doses of estrogens that are now used in postmenopausal women, and women were not studied. Scientists hesitated many years before they accepted that the side benefits of estrogen therapy in postmenopausal women included the long-term prevention of cardiovascular disease.

The short-term benefits of estrogen were recognized early, however, and in the 1960s and 1970s estrogen replacement therapy became increasingly popular. Between 1966 and 1975 the number of prescriptions for estrogen that were dispensed annually doubled.[5] When it became clear that unopposed estrogen replacement therapy was associated with an increased risk of endometrial hyperplasia and cancer,[6,7] however, sales of estrogen dropped abruptly.[5] During the late 1970s the pathogenesis of endometrial hyperplasia was elucidated, and the ability of progestins to antagonize it was discovered. By 1981 the addition of progestins to estrogen therapy had been shown to reduce the incidence of endometrial abnormalities.[8] The use of hormone replacement therapy by postmenopausal women has increased steadily since then.

Many studies have evaluated the long-term safety of estrogen replacement therapy. Most dealt with "unopposed" estrogens because they were used before the introduction of progestin-estrogen combinations. Experience with younger women (i.e., those who use oral contraceptives) has shown that progestins have a range of side benefits and risks that differ markedly from those of estrogens. The new popularity of combined hormone therapy in perimenopausal and postmenopausal women has raised new questions about the overall benefits and risks of such treatment.

Benefits of estrogens

Reduced risk of cardiovascular disease. Overwhelming evidence has been provided by epidemiologic studies of a protective effect of estrogens against cardiovascular disease in women.[9,10] This is true whether the endpoint is myocardial infarction, stroke, or all cardiovascular disease and whether the researchers have studied nonfatal or fatal events or both. Although the results of different studies have varied, the relative risks of cardiovascular disease observed in women who use estrogens have been between 0.2 and 0.7 in prospective

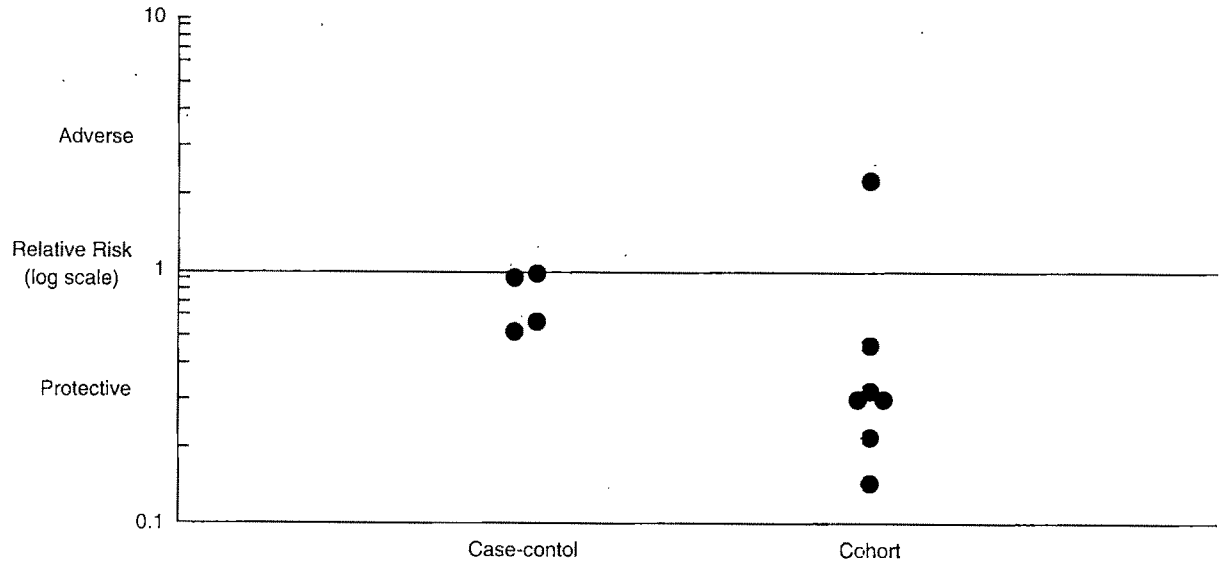

Fig. 1. Relative risks of cardiovascular disease and myocardial infarction in women who use estrogens in retrospective (case-control) and prospective (cohort) studies. Excludes small studies and those based on deaths only. (Data from Ernster et al. Prev Med 1988;17:201-23.)

studies and somewhat higher in retrospective studies (Fig. 1). Studies based only on fatal events have shown similar results.[11] Important cohort studies that have led to this knowledge include the Nurses' Health Study,[11] which followed more than 48,000 women for nearly 338,000 person-years, and found that relative risks in those who used estrogen included 0.56 for major coronary disease, 0.97 for stroke, and 0.72 for total deaths. Another prospective study[12] that followed more than 24,000 women found a relative risk for myocardial infarction of 0.7. Other notable studies include that of the Royal College of General Practitioners[13] (relative risk of myocardial infarction, 0.8); the Leisure World study[14] (relative risk of death from myocardial infarction, 0.47); the Walnut Creek study[15] (relative risk of death from cardiovascular disease, 0.6); the Lipid Research Clinic study[16] (relative risk of death from coronary disease, 0.75 after adjustment for age or 0.99 after adjustment for other risk factors); and the Framingham heart study,[17, 18] in which the relative risks have varied from 0.4 to 2.2, depending on the endpoint, age group, and other risk factors.

Stampfer et al.[12] have recently conducted a meta-analysis of these and other studies of women who use estrogen and showed a summary relative risk of cardiovascular disease in appropriately designed cohort studies of 0.58, whereas other cohort studies together showed higher relative risks. Case-control studies showed the highest relative risks. The authors demonstrated that whereas case-control studies that used population-based controls showed a significantly reduced summary relative risk of 0.76, those that used hospital-based controls showed no such protection. Stampfer et al.[12] and others have argued that this inconsistency is explained by the inadvertent inclusion in hospital-based case-control studies of controls who have conditions that are negatively associated with estrogen use (e.g., fractures).

The protective effect of estrogens against cardiovascular disease does not appear to be explained by the better health of estrogen users, although this point remains controversial.[12] A protective effect has been observed in women of different ages, including older women,[12, 16] smokers, and women who have had an oophorectomy.[12] The protective effect is not clearly related to estrogen dose or duration of use.[12]

Estrogens improve the lipid profile in the direction that is consistent with their beneficial effect on cardiovascular disease. Estrogens increase high-density lipoprotein cholesterol and reduce low-density lipoprotein cholesterol and total cholesterol levels,[19-23] effects that change the risk of cardiovascular disease.[24-27] These effects are seen in women of different ages, in women with and without ovaries, in healthy women, and also in those who have a history of cardiovascular disease. Thus a major proportion of the beneficial action of estrogens is assumed to be through their effects on lipids and subsequently atherosclerosis, although they may also have other effects.

The main cause of death among women (and men) in the United States is cardiovascular disease.[28] Therefore if estrogen replacement therapy resulted in even a small decrease in the relative risk of cardiovascular disease, it would lengthen the life expectancy of a large number of women.

Henderson et al.[29] estimated the beneficial effects of

Fig. 2. Relative risks of cancer of endometrium and breast in women who use estrogen.

estrogens in the number of deaths prevented. At age 65 to 74 years women in the United States would experience approximately 284 per 100,000 fewer deaths annually from coronary artery disease if they currently used estrogen compared with those who do not use estrogen. They also estimated that 49 per 100,000 fewer annual deaths would occur from cerebrovascular accidents, although the relationship with this endpoint to estrogen replacement therapy is now more controversial.[11] One can speculate that the benefit of estrogen replacement therapy might be even greater in smokers, who have a substantially increased risk of cardiovascular disease and are also in greater need of estrogen replacement therapy to prevent osteoporosis.[10]

Reduced risk of osteoporosis and bone fracture. Osteoporosis is a major health problem in elderly women. From 25% to 44% of women experience spontaneous fractures after menopause.[2, 30] Epidemiologic evidence clearly demonstrates that estrogen can retard the development of osteoporosis and substantially decrease the risk of osteoporotic and hip fractures.[11] A minimum of 6 years of estrogen replacement therapy reduces the risk of hip fracture and Colles' fracture by 50%. This protection diminishes after the use of estrogen is stopped. Estrogen protects against fractures of the hip, forearm, and vertebrae.

Henderson et al.[29] estimated that estrogen replacement therapy would reduce the annual mortality rate caused by hip fractures in women in the United States aged 65 to 74 years from 55 per 100,000 to 22 per 100,000.

Long-term risks of estrogen replacement therapy

Increased risk of endometrial cancer. Endometrial cancer ranks third among the most common cancers in women in the United States, with an estimated annual incidence in the range of 39,000 to 42,000 cases.[29, 31] In 1987 alone the National Cancer Institute estimated that 2900 deaths resulted from endometrial cancer and 35,000 new cases of endometrial cancer developed in the United States.[32] Because vaginal bleeding is an early symptom, diagnosis is usually prompt and the prognosis is favorable: the 5-year relative survival rate is 93% among white women with stage I disease and 84% for all stages combined. With or without estrogen treatment, the risk of endometrial carcinoma is known to increase with nulliparity or low parity, obesity, diabetes, and a family history of the disease. It is also recognized that the average age-adjusted incidence rate is significantly higher in white women (21.3/100,000) than in black women (13.1/100,000).[32]

An association between the increasing incidence of endometrial cancer and the increased use of estrogens was made in 1975, when two independent case-control studies[6, 7] reported that the relative risk of endometrial cancer was four to seven times greater among women using estrogen. Since then numerous studies[9] have confirmed this association. Women who use unopposed

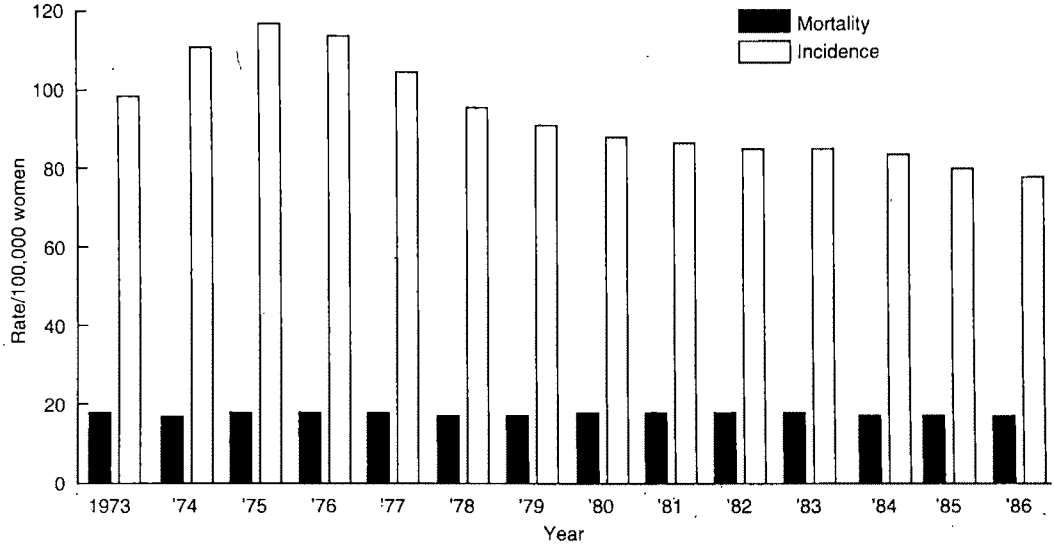

Fig. 3. Mortality caused by and incidence of endometrial cancer in white women in the United States aged more than 50 years, 1973 to 1986. (Source of data: Ries et al.[32])

estrogens have an increased risk of endometrial cancer that depends on the current dose of estrogen (the higher the dose, the higher the risk), the cumulative dose, and the duration of use; the association is consistent whether the study design is prospective or retrospective and is not explained by confounding variables. In women who have used estrogens in the past, the risk of endometrial cancer decreases with increasing time since past use.

Although the relative risk of being diagnosed with endometrial cancer is increased substantially in women who use estrogens (Fig. 2), a part of this increase—perhaps the main part—may be a result of diagnostic bias. Endometrial tumors diagnosed in women who use estrogen are of a lower grade and stage than those in women who do not use estrogen, and the 5-year survival rate (92%) is significantly higher than in women who do not use estrogen (68%).[33, 34] Furthermore, although something of an "epidemic" of endometrial cancer occurred in the late 1960s and early 1970s, and although this declined after 1975 when sales of estrogen were reduced, no changes occurred in the mortality rate caused by the disease over time (Fig. 3). That is, the "epidemic" may have been an artifact, a result of a tendency on the part of pathologists to classify borderline cases of endometrial cancer as malignant if the woman was taking estrogen.

If a causal relationship exists between estrogen use and the excess of endometrial cancer diagnosed in women who use estrogen (and most epidemiologists conclude that such a relationship exists), what public health consequence would result if the mortality rate in each diagnosed woman who uses estrogen was the same as in women who do not use estrogen in whom endometrial cancer is diagnosed? Henderson et al.[29] assumed such a "worst case" approach when they calculated the risk of death that would occur in women who use estrogen replacement therapy. They concluded that among women in the United States aged 65 to 74 years, endometrial cancer would add 26 per 100,000 deaths annually. This number must be balanced against the estimated benefit of 284 per 100,000 deaths from coronary artery disease that are prevented in the same women.

Current knowledge assumes that mortality from endometrial cancer can be redued by an increase in clinical screening and surveillance and that its incidence can be reduced by lowering the rate of obesity. However, compelling evidence shows that the addition of progestins to estrogen replacement therapy is even more useful. Progestin can effectively reduce the occurrence of adenomatous endometrial hyperplasia; at higher doses it can cause regression of preexisting hyperplasia and even of some well-differentiated carcinomas in some patients.[8] Women who take progestins with estrogen are at no increased risk of developing endometrial cancer compared with postmenopausal women who do not take estrogen. Whether the risk is reduced below the risk of an untreated population is unclear. One study[35] suggested this, but more recent work[36] indicates that progestins return the risk of endometrial cancer to that found in women who do not

Table I. Changes in mortality in women aged 65-74 years who receive estrogen or estrogen and progestin

	Change in mortality (per 100,000 women)	
	Estrogen	*Estrogen + progestin*
Hip fractures	−33	−33
Coronary artery disease	−284	−184
Cerebrovascular accident	−49	−32
Endometrial cancer	+26	0
Breast cancer	+38	+38
Total		
With uterus	−302	−211
After hysterectomy	−328	−211

*Modified from Henderson et al. Fertil Steril 1988;49 (suppl):9S-15S. Reproduced with permission of The American Fertility Society.

use progestins. Thus there is a consensus that patients who have an intact uterus should be given progestins in addition to estrogen replacement therapy.[37] The most effective type and dose of progestin and the optimal regimen are still under investigation.[38] No rationale exists for giving progestins to women who have had a hysterectomy.

Breast cancer: Benefit or risk of estrogen?

Approximately 10% of women in the United States will develop breast cancer during their lifetime. The incidence increases with age from 27 per 100,000 at age 30 to 34 years to 422 per 100,000 at age 70 to 74 years. At the time of diagnosis these women experience a 25% reduction in their 5-year survival rate.[32] The National Institutes of Health[32] have estimated that in the United States in 1991 175,000 new cases developed and approximately 44,500 deaths were caused by breast cancer. For women aged 65 to 74 years, the annual mortality caused by breast cancer is 102 per 100,000 women.[29]

Risk factors for postmenopausal breast cancer have been identified as obesity, late age at menopause, late age at first full-term pregnancy, a family history of breast cancer or benign breast disease, and perhaps diet and early age at menarche.[39] A large body of epidemiologic and laboratory evidence links estrogens to breast cancer.[40]

The relationship between breast cancer and estrogen replacement therapy in postmenopausal women is controversial: to date no consensus has been reached, and even the authors of different meta-analyses have reached contradictory conclusions.[41, 42] It is clear, however, that the change in risk caused by estrogen, if any, is quite different from that pertaining to endometrial cancer (Fig. 2). The association between estrogen replacement therapy and endometrial cancer is strong and consistently observed in virtually all studies, but the association between estrogen replacement therapy and breast cancer is weak and inconsistent. Whereas latency and recency of estrogen use affect the risk of developing endometrial cancer, these factors have not been clearly demonstrated in breast cancer. Estrogens have not been associated with any change in the risk of developing breast cancer in women who have taken estrogens for less than 5 years[42, 43] or in women who use conjugated estrogens at a dose of 0.625 or less.[43] Risks seem to be slightly higher in studies conducted in Europe, where synthetic estrogens are used, than in studies conducted in the United States, where most of the estrogen used is conjugated equine estrogen.

On the other hand, the recent meta-analysis by Steinberg et al.[42] has suggested an effect of estrogens in very long-term users; the risk is increased by about 30% after 15 years of use. The same analysis suggested that estrogen replacement therapy might provide a significantly greater relative risk for women who have a family history of breast cancer than for women who do not have such a family history; however, most of the studies on which this conclusion was based used hospital controls, so the finding is difficult to evaluate. The effects of estrogen appeared to be unaltered by parity, benign breast disease, or age at first pregnancy.[42]

Few data on the effects of progestins on breast cancer are available. Studies from Sweden,[44] Denmark,[45] and the United States[46] have shown no evidence for a protective effect of progestins on breast cancer. On the contrary, the relative risk may be slightly higher after several years of combined therapy than after estrogen replacement therapy alone.

One issue that clouds the interpretation of studies of breast cancer and postmenopausal hormone therapy is whether women who use estrogen are screened more frequently and are thus more likely to have their cancer diagnosed early. Evidence for this is controversial. Women who use estrogen are certainly concerned about the risk of breast cancer.[47] Breast tumors diagnosed in women who use estrogen are smaller[48] and carry a better prognosis,[49] which strongly suggests surveillance bias.

Although it is not clear whether the relationship between estrogen and breast cancer is a causal relationship, Henderson et al.[29] conducted a "worst case" analysis to calculate the effect on mortality if such an effect were established. They estimated that estrogen replacement therapy might add about 39 per 100,000 deaths annually in women in the United States aged 65 to 74 years. This must be balanced against the estimated 284 per 100,000 deaths from cardiovascular disease that are prevented in women who receive estrogen replacement therapy.

Balancing the benefits and risks of estrogen therapy

In 1988 Henderson et al.[29] reviewed the pertinent literature on mortality from osteoporotic hip fractures, endometrial cancer, breast cancer, and ischemic heart disease in women aged 65 to 74 years and calculated the hypothetical public health impact of postmenopausal estrogen use. Data on mortality from stroke and revision of the breast cancer data were incorporated into a subsequent analysis (Table I). Annual mortality caused by breast cancer and endometrial cancer would be 38 per 100,000 and 26 per 100,000 higher, respectively, among women who use estrogen versus women who don't use estrogen. Thus total mortality from the two causes that represent the main risks of unopposed estrogen use would be 64 per 10,000 higher in women who use estrogen. On the other hand, mortality caused stroke, osteoporotic hip fractures, and ischemic heart disease would be decreased by 49 per 100,000, 33 per 100,000, and 284 per 100,000, respectively. Thus total mortality from these three major benefits of estrogen would be 366 per 100,000 lower in women who use estrogen. Using this formula, Ross et al.[50] concluded that the predicted annual reduction in mortality among 65- to 74-year-old women who use estrogen was 302 per 100,000 in women who have not had hysterectomies and 328 per 100,000 in women who have had hysterectomies.

A similar formula was used to calculate the difference between mortality in women who use estrogen alone and women who use a combination of estrogen and progestin. This estimate showed that mortality from cardiovascular disease would be lower with estrogen alone than with estrogen and progestin, but that mortality from endometrial cancer would be slightly higher with estrogen alone. Mortality from hip fractures and breast cancer was assumed to be similar with both regimens. These calculations estimated that the addition of progestins to estrogen replacement therapy would reduce the total annual decrease in mortality among women from 302 to 328 per 100,000 to 211 per 100,000 women.

In postmenopausal women mortality from cardiovascular disease is many times higher than mortality from breast cancer,[51] and this difference increases with increasing age. Although replacement therapy may involve an increased risk of breast cancer, this risk is quite small. It is strongly outweighed by the beneficial effects of therapy in preventing cardiovascular disease and osteoporosis.

The effect of sex steroids on the skeleton in premenopausal women

Robert Lindsay, MB, ChB, PhD, FRCP
West Haverstraw and New York, New York

Whereas peak bone mass is genetically determined, the skeletal growth, maturation, and maintenance required to reach this peak may be influenced by physical activity, ovarian function, and nutrition. Estrogen deficiency at menopause leads to increased skeletal remodeling and loss of bone mass, which can result in osteoporotic fractures. Entering menopause with low bone mass is a risk factor itself, because bone mass predicts future risk of fracture. The administration of exogenous steroids can reverse the setting of the "mechanostat" to lower levels after ovarian dysfunction, although it is unclear whether oral contraceptives can modify bone mass in the ovulatory premenopausal woman. Our recent data suggest that the use of steroidal hormones to treat menstrual irregularity (presumably relative to ovarian dysfunction), as opposed to fertility control, is more likely to positively affect bone mass. It is even less clear whether hyperestrogenic states (e.g., pregnancy) affect the skeleton. Recent evidence from bone mass changes that occur in women with ovulatory cycles and inadequate luteal phase function suggests that progestins may also influence skeletal metabolism. (Am J Obstet Gynecol 1992;166:1993-6.)

Key words: Peak bone mass, ovarian function, osteoporotic fractures

Bone mass or density in adult life is the algebraic sum of the amount of bone mass accumulated during growth and its subsequent alteration by a variety of factors that change skeletal behavior and modify bone mass. The best known factor is cessation of ovarian function at menopause, which increases skeletal remodeling and accelerates the rate of bone loss.[1-6] The consequence—increased risk of osteoporotic fractures among postmenopausal women—is equally well known. Increasing evidence indicates that entering menopause with low bone mass is itself a risk factor, because bone mass at any time can predict future fracture risk. To date comparatively little attention has been given to those factors that might modify skeletal mass in premenopausal women and alter their risk of osteoporotic fracture before they enter menopause. Onset of menopause would then become a signal for the physician to evaluate the patient's potential risk of fracture. This review evaluates the factors that might change skeletal mass and thereby alter skeletal integrity in women before they reach menopause.

Peak bone mass

Although the amount of bone in the skeleton at the end of linear growth is primarily genetically determined,[6] the potential to reach peak bone mass may be modified by several factors. Many of these factors are similar to those that are known to modify skeletal mass in adult life, including nutrition, physical activity, and intercurrent illness. The importance of these factors has been determined mainly by studying the effects of extremes. For example, paralysis during childhood leads to development of bone mass that, while adequate for the stress placed on the skeleton in a paralyzed person, is clearly inadequate to withstand the stresses that might be placed on it during normal activity.[7] Extremes of nutritional aberration, such as anorexia and bulimia, deprive the skeleton just as they deprive the remainder of the body of essential nutrients.[8, 9] Malabsorption syndromes effect the same process.[10]

In growing children the roles of nutrition and a normal life-style in modifying peak bone mass have been inadequately studied. Preliminary data from one study[11] suggest that calcium intake increases bone mass in teenagers. In this study the effects of calcium supplements that were given to one twin of a series of monovular twin pairs were examined. The findings reveal greater skeletal mass in the twins who received supplementation. However, it is as yet unknown whether the subjects who have faster accretion will subsequently develop maximal (or peak) skeletal mass greater than that developed by the nonsupplemented twin. Thus the study will be incomplete until all twins have reached peak skeletal mass.

The extent to which peak skeletal mass depends on physical activity within the normal ranges for growing children and teenagers is also unclear.[12] Again, this is-

sue has been inadequately studied, and it would be a difficult study to design and complete. Experience from adult studies is mixed and depends on the stage at which the patient was examined. Given this, and the fact that the processes of skeletal modeling and linear growth proceed in tandem in the young skeleton, it appears likely that changes in physical activity would cause greater changes in skeletal turnover at this stage of life than at an older age. This hypothesis requires further testing.

The capacity to achieve peak skeletal mass probably requires the development of adequate endocrine function of the ovaries or testes. Evidence again is obtained from the study of extreme situations. Patients who have ovarian agenesis (Turner's syndrome) have low bone mass and high predisposition to osteoporotic fracture.[13, 14] Patients who have Klinefelter's syndrome also have lower than normal bone mass.[15] In addition to the effects of the failure to develop mature ovaries, as seen in ovarian agenesis, there may be additional effects on the skeleton because linear growth is reduced and bone mass may be less than average before the normal age of menarche.[16]

Bone mass reduction

Some data indicate that age at menarche may be a determinant of adult bone mass, but further study is required because all the data do not agree.[17] Ovarian function after menarche may also control skeletal status.[18] Several studies[19, 20] have shown that a reduction in bone mass accompanies loss of ovarian function in premenopausal women. Women with exercise-induced amenorrhea have reduced bone mass compared with those who exercise equally but have intact ovarian function.[19, 21-25] However, most studies also indicate that bone mass is greater in women who exercise than in sedentary women who have normal ovarian function. In this circumstance the degree of reduction in mass is related to the duration and extent of ovarian insufficiency.[12] Thus moderate oligomenorrhea is associated with a more modest reduction in mass than complete loss of ovarian activity for a similar duration. It is unclear to what extent these relatively small reductions in bone mass increase the risk of osteoporotic fractures among these women after menopause. When the criterion of bone mass is strictly used—because bone mass is still above the average for healthy, premenopausal women—it does not appear to be a problem. However, the risk of injury and peripheral fractures (so-called stress fractures) appears to be increased among amenorrheic athletes,[20, 26] and therefore further study of this issue is warranted.

Other causes of reduced ovarian function also result in low bone mass. Hyperprolactinemia, for example, causes low bone mass only when it is sufficiently severe to reduce the function of the ovaries.[27] The effects of anorexia and bulimia are compounded by the accompanying loss of ovarian function. Recent evidence suggests that even modest alterations in ovarian function can produce significant changes in the skeleton.[28] The increasing frequency of impaired progesterone production in the second half of the normal ovarian cycle (often called inadequate luteal phase) apparently results in bone mass reduction. This could account for

the variable results seen in cross-sectional studies of bone mass in premenopausal women, in which some studies found evidence of premenopausal bone loss in the spine or femoral neck.[29-31] Again, further evaluation of this issue is necessary. Although nulliparity is often considered a risk factor for postmenopausal osteoporosis, study results are not conclusive.[32] A high frequency of impaired ovarian function that results in infertility might account for the relationship. If nulliparity occurred because of impaired fertility of ovarian origin in the population examined, then that population might be expected to show a higher risk for osteoporotic fracture. This hypothesis remains untested. As ovarian function begins to decline with age, bone loss ensues and the menopausal inflexion in bone mass begins.

The various factors that affect the skeleton are likely to interact. For example, loss of ovarian function complicates the basic dietary problems found in anorectic patients. The theoretic premise for these interactions has been described[33] (Fig. 1). As much as 40% of the bone density variance found in premenopausal women may be explained by variations in physical stress.[34] Differences in calcium nutrition contribute 40% of the variance in bone density of the femoral neck, at least in men.[35] It seems likely that these effects are independent. In our study of women aged 25 to 35 years, all of whom had normal ovarian function, we found that vertebral bone density was higher in situations in which high calcium intake was combined with high levels of physical activity.[36] Again, interactions of life-style, nutrition, and ovarian function have been inadequately studied.

Conclusions

Although the amount of bone in the adult skeleton, often called peak bone mass, is primarily genetically controlled, the potential to acquire the genetically programmed amount can be modified by various factors. These factors are similar to the extrinsic factors that are known to modify skeletal mass in mature persons. However, the magnitude of the effects have been inadequately studied. This may be important because the effects produced, for example, by altering diet, life-style, or endocrine function, may be greater or more important in the younger skeleton that in the older skeleton.

The role of progestins in hormone replacement therapy

Rogerio A. Lobo, MD
Los Angeles, California

Long-term estrogen replacement therapy prevents osteoporosis and reduces the risk of cardiovascular disease in postmenopausal women. Progestins are used to prevent endometrial hyperplasia and carcinoma but should not be prescribed for women who have had hysterectomies. Doses that decrease mitotic activity are sufficient. Recent data suggest that a continuous combined regimen of estrogen and progestin may increase bone mass in women who have established osteoporosis. Some progestins may oppose the beneficial effects of estrogen on the cardiovascular system in some women. Critical cardiovascular effects of progestins include a reduction in the serum level of high-density lipoprotein cholesterol and a direct effect on arterial tone, which may be mediated by an attenuation of prostacyclin production and other factors. Therefore it is prudent to prescribe the lowest effective dose of a progestin that demonstrates the least metabolic impact. The dose and type of progestin should be balanced with the estrogen component so that the estrogen-dominant metabolic effects prevail. With this approach the difference in mortality rates between women who use unopposed estrogen and women who use estrogen-progestin therapy will be minimized and will make the appropriate sequential addition of progestin an option in postmenopausal hormone replacement therapy. (Am J Obstet Gynecol 1992;166:1997-2004.)

Key words: Progestins, hormone replacement therapy, menopause, estrogen

It is well established that the adverse effects of the cessation of ovarian estrogen secretion in postmenopausal women can be ameliorated or reversed by estrogen replacement therapy. The effects of estrogen on osteoporotic bone fracture and cardiovascular disease are of major clinical importance. Estrogen prevents the accelerated loss of bone mass[1] and thereby reduces the risk of osteoporotic fracture by 50% to 60%.[2, 3] Estrogen also protects against cardiovascular disease and coronary heart disease, in part because of its beneficial effect on lipoprotein metabolism.[4] Atherogenic changes in the lipid profile occur as estrogen levels are reduced in early menopause; serum concentrations of total cholesterol and low-density lipoprotein cholesterol (LDL-C) increase, and these are the principal findings. However, serum triglyceride levels have also been found to increase, and high-density lipoprotein cholesterol (HDL-C) levels may also decrease.[5] Exogenous estrogen reverses these changes[6] and decreases the relative risk of coronary heart disease in postmenopausal women to 0.5 compared with women who do not use estrogen.[7, 8]

On the other hand, postmenopausal women who receive unopposed estrogen therapy have an increased incidence of hyperplasia, which may progress to endometrial adenocarcinoma under the continued influence of estrogen.[9] This association of unopposed estrogen and endometrial cancer has been demonstrated in 17 of 19 case-control studies.[4] Compared with the risk in women who do not use estrogen, the relative risk of endometrial cancer is 2.1 after 2 to 5 years of estrogen use and increases to 3.5 after 6 years of use.[10] However, because vaginal bleeding is an early symptom of this disease, there is usually an early diagnosis and a favorable prognosis.

Epidemiologic and histologic studies have clearly demonstrated that the addition of progestins to estrogen replacement therapy not only decreases the risk of endometrial cancer[11, 12, 13] but can also reverse established endometrial hyperplasia to normal endometrium.[14] However, progestins are not without their own untoward side effects. Although it is known that progestins attenuate the estrogen-induced elevation in HDL-C levels that are associated with decreased risk of cardiovascular disease,[15-17] it is unlikely that changes in the lipoprotein profile are solely responsible for the cardioprotective effects of estrogen. Estrogens may have other direct or indirect effects on the cardiovascular system, and some of these effects may be inhibited by progestins as well.[18, 19] Because the option of adding progestins to a postmenopausal replacement hormone regimen has significant public health consequences, data that bears on the effect of progestins must be reviewed from the perspective of the pharmacokinetic,

pharmacodynamic, biochemical, and histologic action of various progestins with regard to their clinical impact. Differences in the activities of specific progestins, minimal effective doses, and optimal duration of therapy will be discussed so their role in postmenopausal hormone replacement therapy can be reevaluated under more appropriate conditions of use.

Role of progestins in endometrial cancer

The biochemical effects of estrogen that are associated with histologically confirmed endometrial hyperplasia and the attenuating effects of progestins that result in a secretory-phase endometrium in postmenopausal women were elucidated by Whitehead et al.[20] These investigators demonstrated that the potent stimulation of conjugated equine estrogens (Cee) (either 0.625 or 1.25 mg/day) that resulted in a proliferative-phase endometrium were associated with increases in (1) deoxyribonucleic acid synthesis and mitotic activity (as reflected in the epithelial glandular labeling index), (2) levels of nuclear estradiol receptors, and (3) levels of soluble progesterone receptors and decreases in estradiol and isocitric dehydrogenase activities. Progestational stimulation that resulted in a secretory-phase endometrium occurred after the addition of norethindrone (NET) (1.0, 2.5, or 5.0 mg daily) or norgestrel (150 or 500 μg daily) for the last 10 days of each month. This was associated with significant reduction of the labeling index and nuclear estradiol receptors to within or below the secretory-phase range and significantly increased activity of estradiol dehydrogenase and isocitric dehydrogenase. This showed that these progestins were capable of biochemically protecting the endometrium against the proliferative effects of estrogen.

This study was continued and expanded by King and Whitehead,[21] who analyzed the biochemical and morphologic effects of 6 to 12 days of treatment with three dose levels of each of five orally administered progestins on the endometrium of estrogen-treated postmenopausal women. After 6 days of progestin administration, the biochemical effects were assessed by means of the above analytes, and the morphology was evaluated by means of the secretory histologic features, subnuclear gylcogen content, presence of giant mitochondria, and appearance of the nucleolar channel system. From these data the oral dose of each progestin required to elicit morphology and biochemistry comparable with a secretory-phase endometrium was determined (Table I). After relating the effects of the progestins to a standardized value for NET and converting the potency of dl-norgestrel to that of levonorgestrel for comparative purposes, it was concluded that levonorgestrel is approximately eight times as potent as NET, with medroxyprogesterone acetate (MPA) and progesterone demonstrating 9% and 0.2% the activity of NET, respectively. Estimations of the oral potencies of these progestins were in general agreement with those calculated by means of different methods. However, although these data are a valuable contribution to our understanding of relative potencies, the potency of MPA may have been underestimated because of pharmacodynamic and bioavailability problems with the MPA preparation that was studied.

The dose and duration of progestin treatment are critical to its effect in ameliorating estrogen-induced hyperplasia. These data were obtained on the basis of biochemical and morphologic analyses after only 6 days of progestin administration, although Paterson et al.[18] had previously shown that the effect of progestins in attenuating the effects of estrogen on the endometrium was optimal if the progestin was administered for more than 10 days per month. On the other hand, Gibbons et al.[22] reported that the relationship between doses of 0.3, 0.625, and 1.25 mg of CEE and the increase in cytosolic estrogen receptor concentration from baseline levels was linear. However, in women who use daily doses of either 0.3 or 0.625 mg of CEE, doses of 2.5, 5, and 10 mg of MPA were all equally successful in reducing estradiol receptor concentrations to pretreatment levels, whereas if the CEE dose were raised to 1.25 mg/day, only 5 or 10 mg of MPA was effective in reducing estradiol receptor concentrations (Fig. 1). These investigators also demonstrated a nonparallelism between the biochemical and the morphologic effects of progestins on the endometrium: although 5 and 10 mg of MPA had identical biochemical effects, only 10 mg of MPA produced a morphologically secretory endometrium. They suggested that eliciting secretory changes in the endometrium is probably unnecessary for the inhibition of hyperplasia and considered it more appropriate to strive for a balance of estrogen and progesterone doses that decrease mitotic activity without inducing full secretory changes. This balance has the further advantage of reducing bleeding.

Effect of progestins on lipid metabolism

As a consequence of menopause, serum levels of total cholesterol, LDL-C, and triglycerides increase significantly and HDL-C decreases significantly, which contributes to a more atherogenic lipid profile.[5,23] The cardiovascular benefits of estrogens have been demonstrated in epidemiologic studies, which show that estrogen replacement therapy decreases the relative risk of death from myocardial infarction to 0.59 and the relative risk of coronary heart disease to 0.5 compared with the relative risk of 1.0 for nonusers.[7,24] The

*Dose tested (mg) that best fits all the parameters analyzed.

presumption has been that alterations in lipid metabolism alone are responsible for the observed decrease in cardiovascular risk that is associated with estrogen replacement therapy in postmenopausal women. However, a residual 30% reduction in the mortality rate for cardiovascular disease occurred after HDL-C was factored into the original multivariate analysis of the Lipid Research Clinics study data. These earlier data that suggest that other factors are involved in the cause of cardiovascular disease have been further refined by newer data from Bush et al.,[25] which now suggest that the HDL-C effect may only explain 30% to 40% of the benefit.[25, 26]

Extensive studies of progestins as components of oral contraceptives have clearly demonstrated that progestins attenuate the estrogen-induced increases of HDL-C and HDL_2-C in women of reproductive age and that their activity is related to the dose and androgenicity of the progestin.[27-30] Therefore when progestins were added to the estrogen replacement therapy to decrease the risk of endometrial hyperplasia and cancer, the effect of the added progestin on the lipid profile was investigated. One study revealed that sequential doses of norgestrel (250 μg) and to a lesser extent MPA (10 mg) reversed the elevated levels of HDL-C and HDL_2-C in postmenopausal women who were treated with 2 mg of estradiol valerate per day.[15] Sherwin and Gelfand[17] determined that the addition of progestin results in a dose-related reduction in the beneficial effect of estrogen on plasma lipids. HDL-C levels were significantly above pretreatment values in postmenopausal subjects who received 1.25 mg of CEE with or without the addition of MPA (5 mg) sequentially for 1 year (Table II). The HDL-C/LDL-C ratio, which is considered a reliable antiatherogenic index, also increased above pretherapy levels in the high-dose CEE group, irrespective of the addition of MPA. A recent review of the effects of postmenopausal estrogen with and without the addition of progestin on serum lipids shows that estrogen-induced HDL-C increases are attenuated

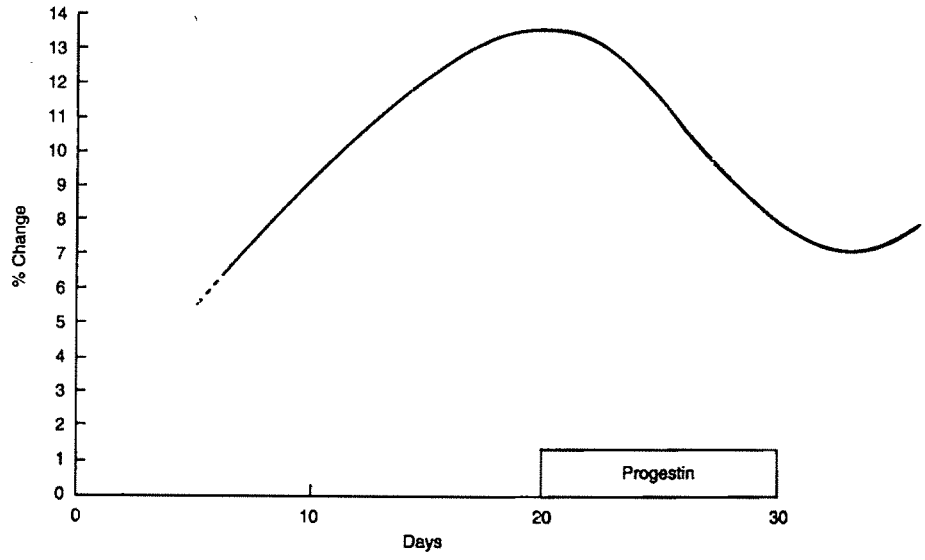

Fig. 2. Attenuation of HDL-C by progestin. Adapted from responses of 0.625 mg CEE, 5 mg MPA, and 1 mg NET. (Modified from Jensen J, et al. Br J Obstet Gynaecol 1986;93:613-8, and Lobo RA. *CEE days 1 to 25; MPA days 15 to 25 (sampling days 18 to 20).

more by levonorgestrel (0.25 mg) than by MPA (10 mg).[31] The data of Jensen et al.[32] and Lobo,[33] however, showed that HDL-C levels increase only 13% to 14% in response to 0.625 mg of CEE and attenuation by either 5 mg of MPA or 1 mg of NET is clinically evident only during the 10 to 12 days of progestin administration. The HDL-C levels were not reduced to baseline levels at any time during the treatment cycle and were increased when progestin administration was discontinued (Fig. 2). Finally, the route of administration plays a role in the effect of the progestin. Estradiol with or without NET acetate was administered to postmenopausal women by the transdermal route, thus eliminating the first-pass effect on the liver. Preliminary results indicated that the transdermal patch, which delivered 0.2 to 0.3 mg of NET acetate per day, had no significant adverse effect on serum lipid levels.[34]

Thus evidence shows that the degree of attenuation of lipid effects by the addition of progestins to estrogen replacement therapy depends on the type or androgenicity of the progestin, the doses of both the estrogen and the progestin, the regimen, and the route of administration.

Other biochemical factors contributing to cardiovascular disease

The effect of progestins on the risk of cardiovascular disease, however, is clearly not restricted to their impact on lipid metabolism. Although the relative importance of other biochemical factors is unclear, these factors undoubtedly have a role in progestin's attenuation of the cardioprotective effect of estrogen and therefore require further elucidation.

It is known that estrogen increases uterine blood flow in the animal model[35] and that progesterone (administered either intramuscularly or by intraarterial infusion) inhibits this response.[18, 36] It has been speculated that the partial depletion of cytoplasmic estrogen receptors, a known effect of progestins that reduces the sensitivity of the uterus to subsequent estrogen action,[37] may contribute to the mechanism of this inhibition.[18] This suggests that the depletion of estrogen receptors by progestins plays a role in cardiovascular disease by regulating blood flow.

Progestins may also contribute to thrombosis by shifting the balance in prostaglandin synthesis. Prostacyclin

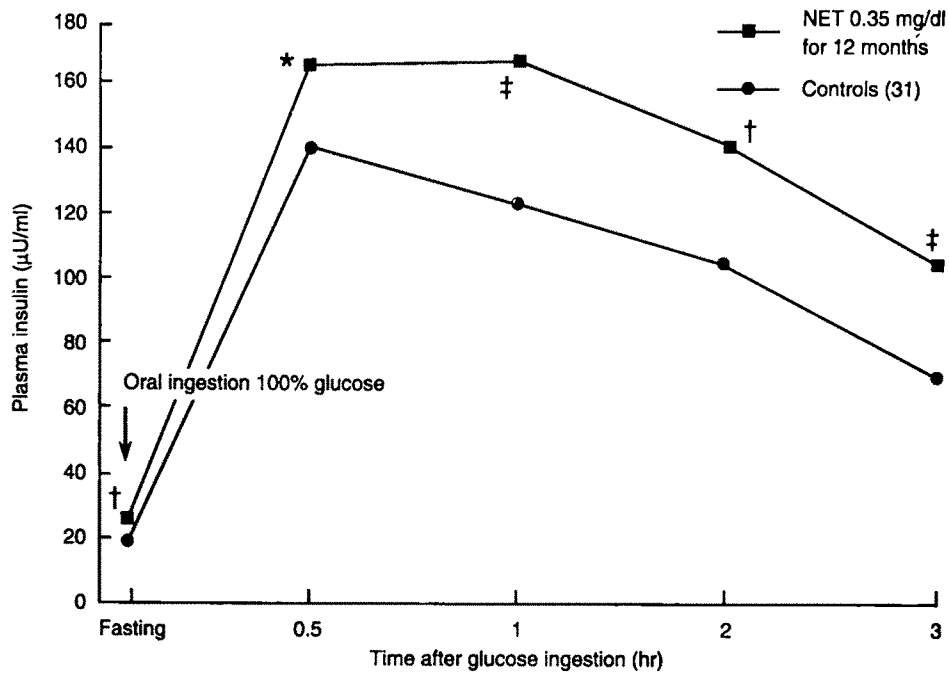

Fig. 3. Effect of NET on carbohydrate metabolism. $*p < 0.05$; $\dagger p < 0.01$; $\ddagger p < 0.001$. Conversion factor for insulin from conventional (μU/ml) to Système International units (pmol/L) is 7.175. (From Spellacy WN, et al. Obstet Gynecol 1975;46:560-3. Reprinted with permission from The American College of Obstetricians and Gynecologists.)

is a potent inhibitor of platelet aggregation and causes vasodilation, and thromboxane is its endogenous antagonist. Therefore a balance between the two may regulate vascular tone and platelet vascular interaction.[38, 39] When progestin is added to estrogen replacement therapy this balance shifts slightly toward thromboxane dominance, which theoretically increases the risk of thrombosis.[19, 40]

Whereas it is clear that both estrogens and progestins influence vasomotor tone, blood coagulation, and blood flow, the precise mechanisms involved require further investigation. Sarrel[41] has recently reviewed the current status of knowledge in this field.

Progestins and carbohydrate metabolism

Studies of the effects of oral contraceptives have demonstrated that some combinations of estrogens and progestins affect carbohydrate metabolism. Therefore it is important to recognize not only that the potential risk of diabetes is increased but that hyperinsulinemia is an independent risk factor for cardiovascular disease,[42] with the risk of myocardial infarction in diabetic women twice that of nondiabetic women.[43] In one study combination oral contraceptives increased glucose levels 43% to 61% and insulin levels 12% to 40% above baseline levels in an oral glucose tolerance test, although progestin-only formulations or combined oral contraceptives with desogestrel or low-dose NET as their progestin component had only minor effects on these parameters.[44] In another study, however, NET administered for 12 months at the same dose (0.35 mg) increased plasma insulin levels significantly at each oral glucose tolerance test sampling, whereas blood glucose values remained unchanged, which suggests insulin resistance (Fig. 3).[45] Although the types and doses of estrogen and progestin may differ in hormone replacement therapy, it is probable that the mechanisms by

which they exercise their effects on carbohydrate metabolism are similar.

In summary the addition of progestins to estrogen replacement therapy can have adverse cardiovascular effects by means of the impact of progestins on lipid metabolism, blood flow, and carbohydrate intolerance. To overcome these effects and maintain an overall favorable cardiovascular profile, it is advisable to use sufficient estrogen and minimal progestin. This can best be accomplished by individualizing dose levels according to each patient's biochemical profile.[46]

Effects of progestins on osteoporosis and breast cancer

Few studies have been performed on the long-term effects of hormone replacement therapy on postmenopausal osteoporosis and risk of bone fracture. However, it has been established that postmenopausal bone loss and the risk of osteoporotic fractures can be prevented or greatly reduced by replacement of estrogen alone.[1-3] Some investigators have suggested that progestins alone also protect against osteoporosis.[47, 48] Other studies have shown that estrogens in combination with progestins have an effect on bone similar to that of estrogen alone.[49, 50] A recent study has demonstrated that the daily administration of estradiol (2 mg), NET acetate (1 mg), and calcium (500 mg) significantly increased bone mass in women who had established osteoporosis.[51] Although additional data are needed about the effects of different doses, type of estrogen and progestin, and duration of treatment, this finding holds promise for women who already suffer from postmenopausal osteoporosis.

Ernster et al.[4] reviewed 10 case-control studies of the effect of estrogen on breast cancer and found that the data were inconsistent and controversial. Studies on the effect of estrogens and progestins on breast cancer risk have been conducted in both younger women who use oral contraceptives and in postmenopausal women after combined hormone replacement therapy. Various studies have shown both a protective effect and a detrimental effect of the addition of progestin to estrogen relacement therapy.[52, 53, 54]

The relationship between hormone replacement therapy and breast cancer requires further study before any convincing argument can be made for its benefits and risks.

Psychological effects of mood disturbances

Whereas estrogen has been shown to improve mood and psychological well-being in postmenopausal women, progestins have been shown to have an adverse effect, at least in some women.[17] Again, both the type of dose and duration of progestin use are important variables that contribute to these effects. Therefore reductions in dose and duration of use may be important factors in helping provide an excellent quality of life for postmenopausal women.

Public health impact of adding progestins

Theoretically the appropriate use of progestins in hormone replacement therapy would substantially change the mortality rates in women 65 to 74 years of age.[33] Cumulative mortality data from the Leisure World (Laguna Hills, Calif.) cohort[55] were used to recalculate annualized data to reflect the impact of administering progestins at a lower dose for only 10 days in a 30-day cycle. This recalculation is based on the assumption that the HDL-C effect (which is reduced 50% by progestin) and the changes in blood flow (which serve as a surrogate for the arterial effects of estrogen) only occur for 10 of 30 days during progestin administration. Taken together this accounts for a downward change in the relative risk by 15%. This model suggests that if progestins were appropriately used, the relative risk of death caused by ischemic heart disease would change from 0.50 to 0.57, resulting in an additional 41 deaths per 100,000 women compared with those who use unopposed estrogen (Table III). On the other hand, the relative risk of death caused by endometrial cancer would be reduced from 6.0 to 1.0, which would save 26 lives per 100,000 women. Thus although the use of unopposed estrogen results in a lower overall mortality rate, appropriate sequential addition of low-dose progestins is an option worth considering. Because no firm data are available to date, and on weighing together all the issues, it is my view that progestins should be administered sequentially with use of a lower dose (2.5 to 5 mg of MPA, 1 mg of NET) for only 10 days. Secretory changes of the endometrium should not be a requirement and reductions in endometrial mitotic activity and elimination of hyperplasia should be the focus of treatment. Clearly, as with all hormonal therapy, appropriate monitoring should be carried out, particularly with the use of lower doses of progestins.

Use of two types of estradiol-releasing skin patches for menopausal patients in a tropical climate

Terry McCarthy, MB, BS, FRCS, FRCOG, Vesna Dramusic, MD, DSc, and Shan Ratnam, MD, FRCS, FRCOG

Singapore

As part of a program to evaluate nonoral routes for delivery of estrogen replacement therapy at the National University Hospital, Singapore, we assessed two different 50 μg estradiol patches. The first study (patch A) was terminated because of a high rate of skin reactions. Tests of the components of this patch identified the alcohol carrier as the cause of these reactions when combined with an occlusive membrane in the tropical Singapore climate. A subsequent clinical trial with 21 female subjects was undertaken with a different 50 μg estradiol patch (patch B). Twenty patients completed the 6-month study. Patch B was as effective as patch A, caused fewer skin reactions, and adhered better. (Am J Obstet Gynecol 1992;166:2005-10.)

Key words: Transdermal estrogen patch, estradiol, skin reactions

Transdermal patches provide an accepted route of delivery for hormone replacement in Europe and the United States.[1, 2] The advantages of transdermal patches include a controlled, sustained release of estrogen,[3] predictable absorption,[4] lack of gastrointestinal effects,[5] circumvention of first-pass circulation through the liver,[6] lower biliary cholesterol saturation index,[7] and slower metabolism to less-active estrogens,[8] which enables maintenance of therapeutic blood levels with a lower total dose of estrogen than in standard oral regimens (e.g., estradiol valerate, 2 mg/day, or conjugated estrogens [Premarin], 0.625 mg/day). At the same time the ability to relieve menopausal symptoms[9] and to protect against osteoporosis[10] is preserved, with significant beneficial effects on high-density lipoprotein/low-density lipoprotein ratios.[11]

The Menopause Clinic of the National University Hospital, Singapore, has a continuing program to evaluate nonoral routes for estrogen administration, which include subdermal implants, patches, and percutaneous creams. In 1986 the Clinic began an informal trial of 50 μg estradiol patches (Estraderm TTS) from Ciba-Geigy AG (Basel, Switzerland). It quickly became apparent that the rate and severity of skin reactions were much higher than had been reported in other series,[12, 13] and the trial was terminated. Four of the women who had experienced skin reactions underwent skin tests in an effort to ascertain which components caused sensitivity. Finally, a formal clinical trial was undertaken to evaluate a different 50 μg estradiol patch from Ortho-Cilag (Schasshausen, Switzerland). These studies are briefly described.

Experience with the Ciba-Geigy 50 μg estradiol patch (patch A)

Sixteen women had been recruited for an evaluation of the Ciba-Geigy 50 μg estradiol patch before the trial was discontinued. Eleven of the women were menopausal (amenorrhea >6 months) and five were perimenopausal, with a mean age of 48.7 years. None of the women had had a hysterectomy. All had been receiving another form of estrogen replacement, and 14 were also taking cyclical progestins (Table I). The patients were instructed to apply the transdermal patch anywhere on their bodies except in the breast area. The patches were changed twice weekly and were used continuously during a 2-month period. In addition to the transdermal estrogen, the women were given progestin on days 1 through 12 of each month (14 women received norethindrone, 1.25 mg, 1 woman received norethindrone, 2.5 mg, and 1 woman received medroxyprogesterone acetate, 5 mg).

Serum estradiol levels were measured during the time of patch use in six women. Five had levels within the normal range for the follicular phase (328.6 ± 120.8 pmol/L); the remaining woman had a level of 99.1 pmol/L, which is a suboptimal therapeutic level.[14]

Because all the women had received oral estrogens before entry into the study, they were able to compare the symptomatic relief obtained with the two regimens. Seven women stopped use of the patch within the first 2 months because they believed it provided less symptomatic relief than did the oral preparation, because of skin reactions.

Adverse skin reactions included itching, discomfort, vesicular rash, erythema, edema, induration, and re-

HRT, Hormone replacement therapy.

sidual pigmentation. Four of 16 patients experienced severe skin reactions,[15] and all reported some itching and redness that increased with duration of use. Skin marks at the site of severe reactions (Fig. 1) often persisted for several weeks (Fig. 2). Two women had residual pigmentation more than 4 months after removal of the patch.

Some women reported that moisture developed under the patch, which resulted in soggy skin and loss of adhesion. Although the patients were not specifically asked about adhesiveness, case records show that at least nine women mentioned that the patches fell off before the expected 3 to 4 days. Only four women chose to continue use of the patches at the end of the trial, although they would have been provided without charge.

Skin tests of components of the Ciba-Geigy patch

Four of the patients who had experienced cutaneous reactions were recalled for skin tests of components of the patch (Table II). The patches were applied in the outpatient clinic and were left in place for 72 hours. Only patches 1 and 6 provided a combination of ethanol and an occlusive membrane; patch 6 also contained estradiol.

Similar reactions were observed in all four patients but were more severe in two.[16] Erythema and itching were most pronounced with patch 1 but also appeared at the site of patch 6 (Fig. 3). Edema was also seen at the site of patch 1 in three patients. In three of the four women one or more patches became dislodged and had to be reapplied. We concluded that the occlusive element combined with ethanol is associated with adverse skin reactions in the hot, humid Singapore climate. The addition of estradiol appeared to alleviate the reactions.

Clinical trial of the Ortho-Cilag 50 μg estradiol patch (patch B)

This study was part of an international trial of the tolerability, adhesiveness, acceptance, and efficacy of transdermal estrogen patches. The patches were designed to release of 50 μg of estradiol every 24 hours and were changed twice weekly (on Mondays and Thursdays). Patients were recruited according to a strict admission protocol. They were to be 50 years of age or older, to have been amenorrheic for at least 12 months, and to have symptoms that were attributable to estrogen deficiency (not necessarily flushes). In addition, they could not have received any hormone re-

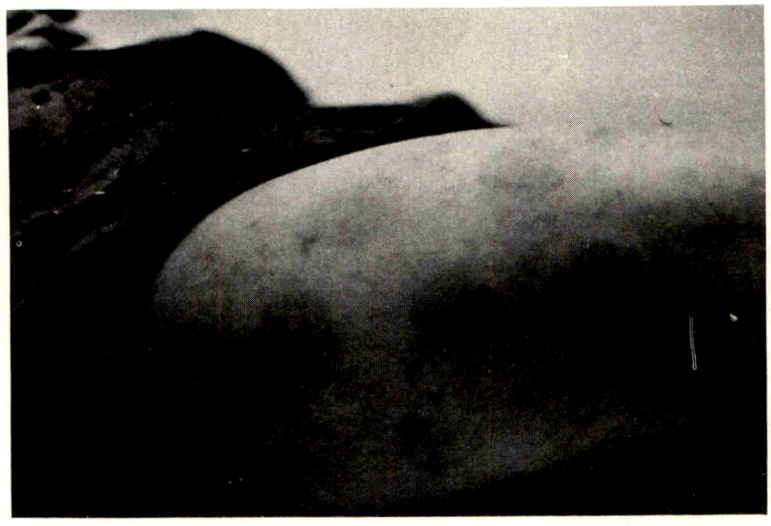

Fig. 2. Persistent skin reactions after removal of 50 μg Estraderm patches (patch A). Because a new patch was applied twice weekly, reactions shown are result of application of patches over 2½ weeks.

placement therapy for at least 2 months before entry to the study, and their uterus had to be in situ. Patients who were allergic to adhesive bandages and those in whom estrogen replacement therapy was contraindicated were excluded.

Each woman was examined in the Menopause Clinic before entering the trial and returned to the clinic once a month for 6 months to complete a detailed questionnaire. At the final visit, 2 weeks after removal of the last patch, each woman completed a questionnaire about acceptability of the patch, and the physician in charge made a global assessment of symptom relief.

Twenty-one women were treated with the Ortho-Cilag 50 μg estradiol patch (patch B). The patches were 16 cm^2 with rounded edges. A monolayered adhesive film that contained the estradiol was located under a transparent occlusive foil backing in each patch. The patches were used for either 3 or 4 days (changed on Mondays and Thursdays) during a 3-week period, followed by a patch-free interval of 1 week in each 28-day cycle. Initially patients were prescribed 0.35 mg of norethindrone on days 10 through 21. Because withdrawal bleeding was minimal or early in most of the cases, this dose was increased to 1.25 mg for 12 days in nine women, with a further increase to 2.5 mg in six women. By the end of the trial 18 of 20 women had withdrawal bleeding, with a mean duration of 5.9 days (range, 2 to 10 days).

This study provided an introduction to estrogen replacement therapy for 14 women, whereas the others had not received treatment for at least 2 months. One patient was erroneously enrolled at the age of 49 years but follow-up was continued according to the protocol. A woman who enrolled as a replacement withdrew in the first week because of a viral illness; at that time she reported that her symptoms of "hotness" were not improved. Thus 20 patients completed the 6-month trial. Their mean age was 53.6 years, with a range of 49 to 59 years (Table III). The mean duration of amenorrhea was 35.8 months (±27.3), and the mean duration of postmenopausal symptoms was 27.6 months (±20.5).

Table II. Summary of components in Estraderm TTS test patch kit

System No.	*Components*
1	TTS placebo (without estradiol) Reservoir with ethanol
2	TTS placebo (without estradiol) Reservoir with methylparaben in water
3	TTS 3M (without estradiol) Nonocclusive Without reservoir
4	TTS 3M (without estradiol) Occlusive Without reservoir
5	TTS PIB (without estradiol) Nonocclusive
6	TTS estradiol, 25 mg Reservoir with ethanol

Eight of 12 patients who had had hot flushes attained complete relief of this symptom by the fourth cycle, and the remaining four women experienced a reduction in intensity of the flushes. The maximum number of flushes per day declined from 25 to 3. The percentage of women who had nocturnal sweating declined from 45% to 30%, and by the sixth cycle only one patient continued to experience this symptom frequently. Similar reductions in depression (45% to 20%), insomnia (65% to 25%), and vaginal burning or itching

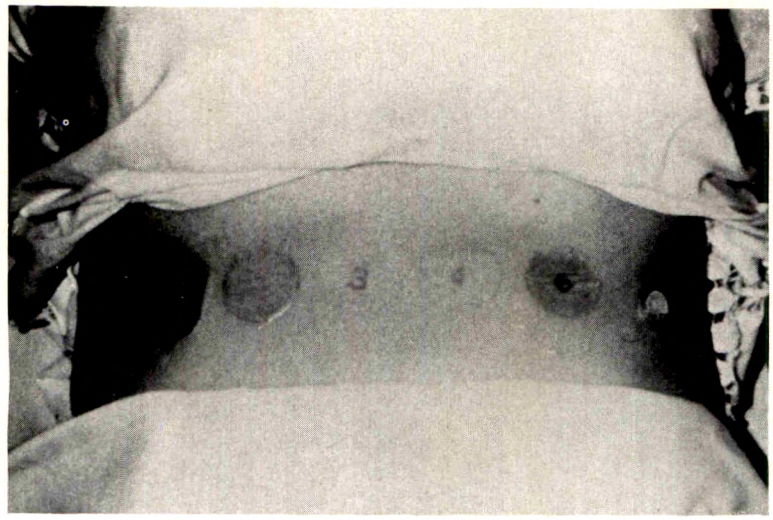

Fig. 3. Sites of application of six individual component patch tests in a patient who had previously experienced adverse reactions with 50 μg Estraderm patches (patch A).

Table III. Summary of the Ortho-Cilag 50 μg estradiol patch study (patch B)

No. of participants	21*

HRT, Hormone replacement therapy.

*One patient withdrew in the first week of use because of viral illness.

†Side effects were not consistently recorded and were limited to one cycle or in eight women.

(30% to 10%) were obtained. According to the physician's global evaluation, 16 (80%) of the patients had very good or good overall improvement of menopausal symptoms (Fig. 4). The lack of response in three patients was attributed to minimal improvements in the other symptoms, including fatigue, nervous irritability, headache, dizziness, and palpitations. A slight but significant ($p < 0.001$) fall in both systolic and diastolic blood pressure also occurred (pretrial: 129.5 [±11.4]/81.6 [±7.9] mm Hg; cycle 6: 116.6 [±11.7]/74.0 [±6.7] mm Hg).

The frequency of erythema at the patch site declined from 11 women in the first cycle to 5 women by the sixth cycle; the mean (±standard deviation) duration of erythema was 1.2 (±0.4) days. Edema ($n = 3$) and eczema ($n = 2$) were reported in the first cycle only. Three of the six women who recorded itching in the first cycle were subsequently symptom free. However, for those women who continued to experience itching by the end of the trial, the mean duration increased from 1.4 to 7.3 (±11) days. The magnitude of the increase resulted from the fact that one patient reported itching for 20 days in the final study cycle.

Only one patient noted a problem with patch adhesion despite full normal activity that included bathing. Some patients commented that a "plaster rim" remained after the patch was removed. Patient acceptance of the Ortho-Cilag patch was high. All 20 patients found that it was comfortable and nonobstructive. It did not interfere with clothing or disturb the skin. Seventeen (85%) expressed willingness to continue use of this method of estrogen replacement.

Comment

Because of differences in study population and method, relief of symptoms from these two clinical trials cannot be directly compared. All of the women who used the Ciba-Geigy patch had already experienced relief of their symptoms from their previous estrogen replacement therapy, whereas in the Ortho-Cilag trial, the patients were either new to therapy or had not received treatment for at least 2 months and experienced symptoms at the start of the trial. This difference could partly account for the greater percentage of patients who wanted to continue use of the Ortho-Cilag patch (85% vs 25%). Another possible source of bias could be that the two study groups had different clinic motivators.

Adequate progestin therapy is necessary to prevent risk of endometrial cancer in women who undergo estrogen replacement therapy.[17] Progestins may, however, be associated with some adverse symptoms. Therefore our general policy is to gradually step up

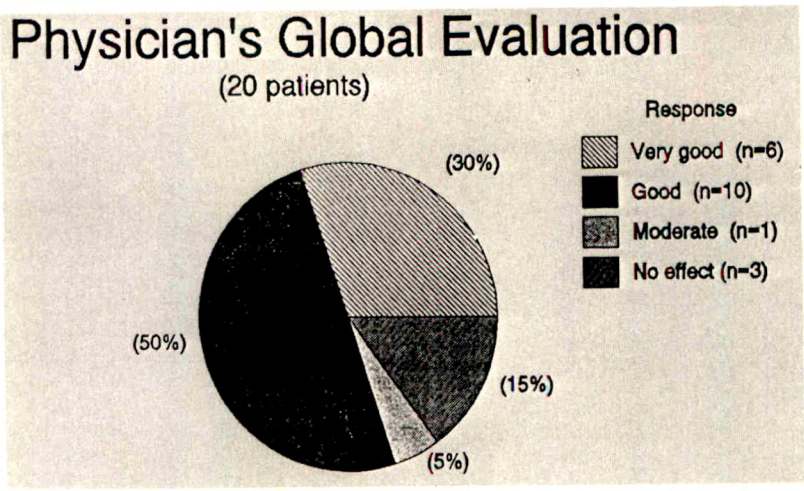

Fig. 4. Physician's global assessment of Ortho-Cilag transdermal estradiol patch after a 6-month trial.

the dosage until withdrawal bleeding occurs only at the end of the progestin exposure.[18] The starting dose of 0.35 mg/24 hr, as supplied for the trial, was too low and was increased in nine patients before the end of the 6-month study period.

We believe that certain conclusions can be drawn from the two studies with regard to adhesive properties of the patches and skin complications. Both products were designed to release 50 μg of estradiol per 24 hours. Furthermore, the racial distribution of the participants and the climate were the same in both studies. Although patients in the first trial were not specifically queried about patch adhesion, nine patients volunteered the fact that patches came off. In the second trial, however, patients were asked about patch adhesion, and only one patient acknowledged loss of patches in three of the six cycles.

The more severe reactions associated with the Ciba-Geigy patches appeared to be related to the combination of a tropical climate, an occlusive membrane, and the alcohol in the reservoir. Accumulation of sweat under patches has been associated with increased skin irritation from other transdermal systems,[19] and reports of unacceptable reactions to the Ciba-Geigy transdermal estradiol patch have also come from Thailand.[20, 21] The Ortho-Cilag patch also has an occlusive element but does not contain ethanol.

Reports of cutaneous reactions from the Ciba-Geigy patch in temperate climates range from none[22] to 35%.[23] Hogan and Maibach[24] cite a frequency of 17% with a 2% discontinuation rate. Holdiness[25] reviewed studies that reported a range of 0% to 36%. Higher rates have been reported in warmer areas of the United States, such as Florida.[26] McBurney et al.[27] reported nine patients in New Orleans who had dermatitis from the Ciba-Geigy patch, which they attributed to delayed contact sensitivity to substances in the system, including the adhesive (mineral oil and polyisobutylene) and the hydroxypropyl cellulose that was used as a gel in the reservoir. Their results were confusing, however, and they concluded that the reactions were to "either the adhesive or the vehicle" and further suggested that the drug reservoir might contain another allergen that caused contact sensitivity. Schwartz and Clendenning[28] reported a reaction to hydroxypropyl cellulose in alcohol and mineral oil but not in water.

The mitigating effect of estradiol observed in the patch component study is of particular interest. Utian[29] reported a much higher rate of cutaneous reactions with use of placebo patches versus estradiol patches. He did not mention, however, whether the placebo patches contained ethanol.

Prolonged pigmentation in two women that was still visible 4 months after removal of the Ciba-Geigy patch was a distressing adverse effect. Because estrogen is associated with increased pigmentation during pregnancy, it is possible that exposure to ultraviolet light and topical estradiol might increase local pigmentation. However, the Ciba-Geigy phototoxicity and photoallergy studies[9] had not demonstrated any potentiation. A recent report[30] of hyperpigmentation in a menopausal woman who was treated with ultraviolet phototherapy for pruritus that was caused by a transdermal estradiol system is of interest because of the analogy to the Singapore climate, although most of our patients would go out of their way to avoid unnecessary exposure to sunlight.

Conclusion

A trial that directly compares the Ortho-Cilag and the Ciba-Geigy 50 μg estradiol patches would provide more valid assessments of the relative efficacy, tolera-

bility, and adhesive properties of the two products. Nevertheless, some general observations can be made from this study. First, both patches are effective in relieving the symptoms of menopause, although they may be slightly less effective than the oral preparations in "equivalent"[31] doses. Second, the Ortho-Cilag patches are considerably less irritating to the skin when used by women who live in Singapore. Third, the Ortho-Cilag patches have better adhesive properties when used by women who live in Singapore. The last two advantages, combined with efficacy comparable with that of the Ciba-Geigy patches, make the Ortho-Cilag 50 μg estradiol transdermal patch more acceptable for use in tropical climates.

We thank Ms. Veronica Yo, the clinic motivator, without whom the trial would not have been possible.

Discussion II

Chairman Mishell. Is it acceptable to give hormone replacement therapy to women who have had endometrial or ovarian cancer more than 5 years earlier?

Dr. McCarthy. Yes. It certainly appears safe to give hormone replacement therapy to women after bilateral oophorectomy for epithelial ovarian cancer, even though there have been some suggestions that the ovary contains estrogen receptors. In a recent study[1] from the Royal Marsden Hospital in the United Kingdom, no significant difference in survival was found between users and nonusers of hormone replacement therapy that was begun at a median of 4 months after diagnosis.

It is somewhat more difficult to make a recommendation for women who have had endometrial cancer, but if the disease was at a very early stage at the time of operation,[2] I believe hormone replacement therapy can be given to such a patient who is clinically free of recurrence after 5 years.

Chairman Mishell. Dr. Lobo, if progestin is given to patients every 3 months instead of every month, will the effects of this steroid be reduced?

Dr. Lobo. I use it selectively. Those patients who cannot or will not take progestin must be monitored. I currently use ultrasound monitoring; when I see excessive proliferative effects, I prescribe progestin in an intermittent form. Although we do not yet have long-term data, I believe this is an appropriate procedure for managing those patients.

With the current medicolegal climate in the United States, an additional concern is that those who practice outside of what is normally recommended must take some extra precautions. These patients probably should have biopsies until we are absolutely certain ultrasonography is a safe method of monitoring. However, I am comfortable with the use of ultrasonography.

Chairman Mishell. Do you believe it is necessary to increase the dose of progestin when you give higher doses of estrogen to women who have severe hot flushes?

Dr. Lobo. The study by Gibbons et al.[3] showed that 2.5 mg of medroxyprogesterone acetate was protective, that it prevented the synthesis of the endometrial receptors for 0.625 mg of conjugated equine estrogens, and that 2.5 mg of medroxyprogesterone acetate was not sufficient for 1.25 mg of conjugated equine estrogen. A balance of estrogen and progestin is required. If a large amount of estrogen is used, the progestin must be increased; the size of the increase depends on how much the estrogen is increased.

Chairman Mishell. Dr. Harlap, why do epidemiologists use log scales rather than linear scales for setting the data? Doesn't this minimize the significance of the findings?

Dr. Harlap. It is mathematically more correct to use a log scale in presenting the data. By looking at the results plotted on a log scale, we obtain a "fairer" perception of what the differences mean. The confidence limits of the relative risk are also distributed in a log fashion. As Dr. Grimes pointed out, the relative risk of 0.5 is equal but opposite to a relative risk of 2. Similarly, a change in relative risk from 0.5 to 1 represents a doubling of risk, and a change from 1 to 2 represents a similar doubling.

Chairman Mishell. Dr. Lobo, what is your opinion of giving low-dose oral contraceptives as a means of estrogen replacement to women in developing countries in which estrogen replacement drugs are more expensive than oral contraceptives?

Dr. Lobo. Age is the deciding factor. If the patient has premature ovarian failure, I believe it is an acceptable practice. I would not give a low-dose oral contraceptive to a woman who is more than 60 years of age; I believe that is more estrogen than she needs. It is acceptable, however, for a nonsmoking woman to use these low-dose oral contraceptives up to or a little past the age of 45 years. However, if you look at dose equivalencies, even 30 μg of ethinyl estradiol in the pill is close to about 3 mg of conjugated equine estrogen, and that is much more than is really needed. As we have said several times the risk here is thrombosis and not atherosclerosis.

Dr. McCarthy. I would like to add a point regarding the price of estrogen replacement therapy, which must be balanced against the savings achieved when it is used in prophylactic treatment. Given that perspective, having a number of women who use estrogen will provide a savings to any society.

Chairman Mishell. Your data show that hormone replacement therapy saves lives, Dr. Harlap, but for how long, and with what quality of extended life?

Dr. Harlap. The question relates to the value of women to society. A woman aged 60 years or more whose health is preserved can be a valuable member of society both in developing and developed countries. That it is beneficial to postpone death and to increase productive or valuable life is without question.

6/0/37511

Dr. Lobo. The leading cause of death in women is still cardiovascular disease, but with replacement therapy life can be prolonged for 2½ to 3 years.

Chairman Mishell. Dr. Lobo, no evidence exists that progestin prevents breast cancer. Would you suggest giving it to patients who have had a hysterectomy?

Dr. Lobo. We do not advocate giving progestin to patients who have had a hysterectomy. We do not believe that progestin has a protective effect against breast cancer.

Chairman Mishell. Dr. Lindsay, in what order would you rank the following factors in preventing osteoporosis: exercise, cessation of smoking, a calcium-rich diet (calcium supplementation), and estrogen replacement therapy?

Dr. Lindsay. For postmenopausal women the only effective agent among those listed is estrogen replacement therapy. The evidence is clear that calcium supplementation and exercise do not alone prevent the bone loss caused by ovarian insufficiency. Nonetheless, these factors improve general health and thus have beneficial effects beyond the effects on the skeleton. In treating patients the physician should recommend a reasonable program of physical activity, discourage smoking, and ensure that calcium deficiency does not exacerbate the effects of estrogen deprivation. Patients should obtain between 1000 and 1500 mg of calcium per day, preferably from dietary sources.

Chairman Mishell. Would steroid treatment benefit a woman who is already 10 years postmenopausal and has not previously received this treatment?

Dr. Lindsay. There appears to be some doubt in the literature, or at least in clinicians' minds, about the value of estrogen intervention in older patients or in patients who already have clinical osteoporosis. However, several studies[4] have demonstrated that replacement therapy protects women up to age 75 years and those with established osteoporosis against further bone loss. Estrogen intervention is the first-line therapy for osteoporosis in women who are at least 75 years of age.

Chairman Mishell. Dr. McCarthy, could you comment on the advantages or disadvantages of transdermal estrogen versus oral estrogen?

Dr. McCarthy. I made two general points about the absence of the first pass to the liver and the fact that a constant level in the blood is present rather than an up-and-down effect. I believe both those effects are well established. The advantages and relative advantages and disadvantages are being assessed.

Chairman Mishell. Dr. McCarthy, you discussed the regulation of estrogens by membrane. In the matrix patch the skin is the only straight filter. Were any differences in plasma estradiol levels obtained with the two patch systems?

Dr. McCarthy. Ours was not a direct comparison between the two transdermal systems. After our adverse experience with the initial patch we thought that many patients might withdraw in the middle of the trial; therefore we studied only 20 patients. We were mainly interested in the acceptability and did not measure serum estradiol levels in the second series.

Chairman Mishell. Another question that arose is: Why not give estrogen to men because of its protective effects against coronary heart disease? I believe the answer is that it stimulates breast growth and increases the risk of breast cancer in men. I believe other agents exist that can affect the lipids beneficially.

Another question that arose is whether estrogen replacement can be given routinely to all women on a prophylactic basis; I believe this can be done.

Participant. I agree. We basically have full proof of the protective effect; a recent article in the *New England Journal of Medicine* (1991;325:756-62) confirms that proof.

IN THE MANAGEMENT OF ENDOMETRIOSIS

enough is enough

Lasting resolution of symptoms

- Suppresses estradiol to levels required for effective relief.[1]
- 92% of patients taking SYNAREL, 400 μg/day, were either symptom-free (60%) or had only mild symptoms (32%) at the end of 6 months of treatment (n=73).
- Pregnancy should be ruled out before therapy with SYNAREL is initiated, and patients should be advised to use a nonhormonal method of contraception when taking SYNAREL.
- Retreatment cannot be recommended since safety data for retreatment are not currently available.

The safety of a rapidly cleared drug

- Facilitates immediate termination of treatment in the event of drug-related adverse effects, with drug clearance occurring in less than 1 day.
- The most frequent side effects with SYNAREL are those associated with hypoestrogenism.
- There is a small loss in bone density with 6-month treatment, some of which may not be reversible. During one treatment period, this bone loss should not be important.

SYNAREL® (NAFARELIN ACETATE) NASAL SOLUTION, 2 MG/ML

Satisfying the promise of GnRH* analog therapy

1. Syntex document #829-365-A.

*Gonadotropin-releasing hormone.

Please see brief summary of prescribing information on next page.

BRIEF SUMMARY

SYNAREL® Nasal Solution contains nafarelin acetate (2 mg/mL, expressed as nafarelin base), benzalkonium chloride, glacial acetic acid, sodium hydroxide or hydrochloric acid, sorbitol, and purified water.

INDICATIONS AND USAGE: For management of endometriosis. Experience is limited to women 18 years and older treated for 6 months.

CONTRAINDICATIONS: Hypersensitivity to GnRH, GnRH agonist analogs or any excipients in SYNAREL; undiagnosed abnormal vaginal bleeding; pregnancy or possibility of pregnancy while taking the drug because SYNAREL may cause fetal harm when administered to a pregnant woman. If SYNAREL is used during pregnancy or if the patient becomes pregnant while taking this drug, she should be apprised of the potential hazard to the fetus; use in women who are breast feeding.

WARNINGS: Safe use in pregnancy has not been established clinically. Before starting treatment pregnancy must be excluded.

When used regularly at the recommended dose, SYNAREL usually inhibits ovulation and stops menstruation. Contraception is not insured, particularly if patients miss successive doses. Therefore, patients should use nonhormonal contraception. Advise patients to see their physician if they believe they may be pregnant. If a patient becomes pregnant during treatment, discontinue the drug; apprise patient of the potential risk to the fetus.

PRECAUTIONS General: Ovarian cysts have been reported in the first 2 months of therapy. These may resolve spontaneously or may require drug discontinuation or surgery.

Information for Patients: 1. Since menstruation should stop with SYNAREL, the patient should notify her physician if regular menstruation persists. If patient is compliant and menstruation persists to second month, consider doubling the dose. Counsel noncompliant patients on importance of taking SYNAREL regularly. 2. Patients should not use SYNAREL if pregnant, breast feeding, have undiagnosed abnormal vaginal bleeding, or are allergic to any of its ingredients. 3. Safe use in pregnancy has not been established. Therefore, a nonhormonal method of contraception should be used during treatment. If a patient becomes pregnant during treatment, she should discontinue the drug and consult her physician. 4. Adverse events occurring most frequently in clinical studies are associated with hypoestrogenism. Nasal irritation occurred in about 10% of patients. 5. Induced hypoestrogenic state results in a small loss in bone density over a 6-month treatment course. Some of this loss may not be reversible. During one six-month treatment period, this should not be important. In patients with major risk factors for decreased bone mineral content, i.e., chronic alcohol and/or tobacco use, strong family history of osteoporosis, or chronic use of drugs that can reduce bone mass such as anticonvulsants or corticosteroids, SYNAREL may pose additional risk. In these patients risks and benefits must be weighed carefully. Repeated courses of treatment with GnRH analogs are not advisable in patients with major risk factors for loss of bone mineral content. 6. Patients with intercurrent rhinitis should consult their physician for use of a topical nasal decongestant. If a topical nasal decongestant is required during treatment, it must be used at least 30 minutes after SYNAREL dosing to decrease the possibility of reducing drug absorption. 7. Retreatment cannot be recommended since safety data beyond 6 months are not available.

Drug Interactions: No pharmacokinetic-based drug-drug interaction studies have been conducted. Nafarelin acetate is a peptide primarily degraded by peptidase and not by cytochrome P-450 enzymes, and is only about 80% bound to plasma proteins at 4°C; therefore drug interactions would not be expected to occur.

Drug/Laboratory Test Interactions: SYNAREL in therapeutic doses suppresses the pituitary-gonadal system. Normal function is usually restored 4-8 weeks after treatment is discontinued. Therefore, diagnostic tests of pituitary gonadotropic and gonadal functions during treatment and up to 4-8 weeks after discontinuation of SYNAREL may be misleading.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Carcinogenicity studies were conducted in rats and mice at intramuscular doses up to 110 times and 560 times the maximum recommended human intranasal dose, respectively. These multiples of the human dose are based on the relative bioavailability of the drug by the two routes of administration. As with other GnRH agonists, nafarelin acetate given to laboratory rodents at high doses for prolonged periods induced hyperplasia and/or neoplasia of endocrine organs. At 24 months, there was an increase in the incidence of pituitary tumors (adenoma/carcinoma) in high-dose female rats and a dose-related increase in male rats. There was an increase in pancreatic islet cell adenomas in both sexes, and in benign testicular and ovarian tumors in the treated groups. There was a dose-related increase in benign adrenal medullary tumors in treated female rats. In mice, there was a dose-related increase in Harderian gland tumors in males and an increase in pituitary adenomas in high-dose females. No metastases of these tumors were observed. It is known that tumorigenicity in rodents is particularly sensitive to hormonal stimulation.

Mutagenicity studies using bacterial, yeast, and mammalian systems provided no evidence of mutagenic potential.

Reproduction studies in male and female rats have shown full reversibility of fertility suppression when treatment was discontinued after continuous administration for up to 6 months.

Pregnancy, Teratogenic Effects: *Pregnancy Category X.* Intramuscular SYNAREL was administered to rats throughout gestation at about 0.5, 2, and 7 times the maximum recommended human intranasal dose based on the relative bioavailability by the two routes of administration. An increase in major fetal abnormalities was seen in 4/80 fetuses at the highest dose. A similar study at the same doses in rats and studies in mice and rabbits at doses up to 600 μg/kg/day and 0.18 μg/kg/day, respectively, failed to demonstrate an increase in fetal abnormalities after administration throughout gestation. In rats and rabbits, there was a dose-related increase in fetal mortality and a decrease in fetal weight with the highest dose.

Nursing Mothers: It is not known whether SYNAREL is excreted in human milk. Because many drugs are excreted in human milk, and because the effects of SYNAREL on lactation and/or the breastfed child have not been determined, SYNAREL should not be used by nursing mothers.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: The most frequently reported adverse reactions were those related to hypoestrogenism. In controlled studies comparing SYNAREL (400 μg/day) and danazol (600 or 800 mg/day), the following adverse reactions were most frequently reported and thought to be drug-related.

Hypoestrogenic: hot flashes (SYNAREL 90%, danazol 69%), decreased libido (22%, 7%), vaginal dryness (19%, 7%), headaches (19%, 21%), emotional lability (15%, 18%), insomnia (8%, 4%); **Androgenic:** acne (13%, 20%), myalgia (10%, 23%), reduced breast size (10%, 16%), edema (8%, 23%), seborrhea (8%, 17%), weight gain (8%, 28%), hirsutism (2%, 6%), increased libido (1%, 6%); **Local:** nasal irritation (10%, 3%); **Miscellaneous:** depression (2%, 5%), weight loss (1%, 3%).

Less than 1% of patients experienced paresthesia, palpitations, chloasma, maculopapular rash, eye pain, urticaria, asthenia, lactation, breast engorgement, and arthralgia. In clinical trials, immediate hypersensitivity thought to be possibly or probably related to nafarelin occurred in 3 (0.2%) of 1509 healthy subjects or patients.

Changes in Bone Density: After 6 months' treatment vertebral trabecular bone density and total vertebral bone mass, measured by quantitative computed tomography (QCT), decreased by an average of 8.7% and 4.3%, respectively, compared to pretreatment levels. There was partial recovery of bone density post-treatment; the average trabecular bone density and total bone mass were 4.9% and 3.3% less than pretreatment levels, respectively. Total vertebral bone mass, measured by dual photon absorptiometry (DPA), decreased by a mean of 5.9% at end of treatment. Mean total vertebral mass, re-examined by DPA 6 months post-treatment, was 1.4% below pretreatment levels. There was little, if any, decrease in the mineral content in compact bone of the distal radius and second metacarpal. Use for longer than the recommended 6 months or in presence of other known risk factors for decreased bone mineral content may cause additional bone loss.

Changes in Laboratory Values: *Plasma enzymes.* During clinical trials SGOT and SGPT levels were more than twice the upper limit of normal in only one patient each. There was no other evidence of abnormal liver function and levels returned to normal after treatment was stopped.

Lipids. At enrollment and at end of treatment, 9% of patients on SYNAREL 400 μg/day and 2% on danazol had total cholesterol values above 250 mg/dL.

Of those with pretreatment cholesterol values below 250 mg/dL, 6% on SYNAREL and 18% on danazol had post-treatment values above 250 mg/dL.

Mean (±SEM) pretreatment values for total cholesterol from all patients were 191.8 (4.3) mg/dL in the SYNAREL group and 193.1 (4.6) mg/dL in the danazol group. At the end of treatment, mean values from all patients were 204.5 (4.8) mg/dL in the SYNAREL group and 207.7 (5.1) mg/dL in the danazol group. These increases from pretreatment values were significant ($p < 0.05$) in both groups.

Triglycerides were increased above the upper limit of 150 mg/dL in 12% of the patients on SYNAREL and in 7% of the patients on danazol.

At the end of treatment, no patients on SYNAREL had abnormally low HDL cholesterol fractions (< 30 mg/dL) compared with 4.3% of patients on danazol. No patients on SYNAREL had abnormally high LDL cholesterol fractions (> 190 mg/dL) compared with 15% of those on danazol. There was no increase in the LDL/HDL ratio in patients on SYNAREL, but approximately a 2-fold increase in the LDL/HDL ratio in patients on danazol.

Other changes. In comparative studies, the following changes were seen in approximately 10% to 15% of patients. SYNAREL was associated with elevations of plasma phosphorous and eosinophil counts, and decreases in serum calcium and WBC counts. Danazol therapy was associated with an increase of hematocrit and WBC.

OVERDOSAGE: At present there is no clinical evidence of adverse effects following overdosage of GnRH analogs.

Genetics is much more than child's play.

A lot of companies offe
laboratory tests. But it'
not easy to find one with
our focused experience i
genetics and infertility.
At the **Genetics & IV**
Institute, we understand
the needs of obstetricians
because we're one of you.
In our well-respected nationa
reference laboratories, your patient
samples get the same attention
and turnaround time as our own.
In prenatal cytogenetics, you benefit from
rapid amniocentesis and one of the world's most
experienced chorionic villus (CVS) labs. We offer
you expertise in Fragile X testing, molecular DNA analysis
for disease/carrier detection and paternity testing, blood
chromosome analysis, and MSAFP and (AFP+) screening.
For treatment of infertility, you can obtain top quality,
genetically screened donor semen from the Fairfax Cryobank,
and order rapid hormone assays 365 days a year. And if you
ever need help with a test result, you consult directly with our
laboratory heads, M.D.s, and counselors.

Contents

July
1992

This issue contains a Clinical Section, a Basic Science Section beginning on page 178, and a Symposium on the Pathophysiology of Infertility Associated with Endometriosis beginning on page 250.

CLINICAL SECTION

Clinical Articles

Continuous combined conjugated equine estrogen-progestogen therapy: Effects of medroxyprogesterone acetate and norethindrone acetate on bleeding patterns and endometrial histologic diagnosis 1

T.C. Hillard, MD, N.C. Siddle, MD, M.I. Whitehead, MD, D.I. Fraser, MD, and J. Pryse-Davies, MD

London, England

Continuous combined estrogen therapy may not be widely acceptable because of a high incidence of chronic bleeding; bleeding patterns may not be predictive of endometrial response.

Macrosomia in postdates pregnancies: The accuracy of routine ultrasonographic screening 7

Raphael N. Pollack, MDCM, Gittit Hauer-Pollack, MSc, and Michael Y. Divon, MD

Bronx, New York

Routine ultrasonographic screening to detect the presence of fetal macrosomia in postdates pregnancies was associated with a positive value of 64%.

The clinical diagnosis of asphyxia responsible for brain damage in the human fetus 11

James A. Low, MD, Lynn L. Simpson, MD, and David A. Ramsey, MB, ChB

Kingston, Ontario, Canada

The diagnosis of antepartum or intrapartum fetal asphyxia that leads to brain damage may be difficult with current means of clinical assessment.

Simplified Gram stain interpretive method for diagnosis of bacterial vaginosis 16

Jessica L. Thomason, MD, Robert J. Anderson, PhD, Sheldon M. Gelbart, PhD, Peter J. Osypowski, MT(ASCP), Nancy J. Scaglione, OGNP, Gamal El Tabbakh, MD, and Janine A. James, MD

Milwaukee, Wisconsin, and Chicago, Illinois

By including clue cells in the Gram stain criteria, it is possible to rapidly diagnose bacterial vaginosis from Gram stains of vaginal secretions without having to count individual bacteria on each stain.

Ethically justified guidelines for family planning interventions to prevent pregnancy in female patients with chronic mental illness 19

Laurence B. McCullough, PhD, John Coverdale, MB, ChB, Timothy Bayer, MD, and Frank A. Chervenak, MD

Houston, Texas, and New York, New York

On the basis of the concept of chronically and variably impaired autonomy, we propose ethically justified clinical guidelines for family planning interventions to prevent pregnancy in female patients with chronic mental illness.

A prospective, controlled multicenter study on the obstetric risks of pregnant women with antiphospholipid antibodies 26

Henk J. Out, MD, Hein W. Bruinse, MD, Godelieve C.M.L. Christiaens, MD, Marja van Vliet, Philip G. de Groot, PhD, H. Karel Nieuwenhuis, MD, and Ronald H.W.M. Derksen, MD

Utrecht, The Netherlands

In a multicenter controlled study it is demonstrated prospectively that the presence of antiphospholipid antibodies is a risk factor for adverse pregnancy outcome.

CEFOTAN® IM/IV

(cefotetan disodium)

Available in 1-gram and 2-gram vials

For Intravenous or Intramuscular Use
PLEASE SEE FULL PRESCRIBING INFORMATION FOR A COMPLETE DESCRIPTION.
A BRIEF SUMMARY FOLLOWS.

INDICATIONS AND USAGE
TREATMENT

CEFOTAN is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:

Urinary Tract Infections caused by *E. coli, Klebsiella* species (including *K. pneumoniae*), *Proteus mirabilis,* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris, Providencia rettgeri,* and *Morganella morganii*).

Lower Respiratory Tract Infections caused by *Streptococcus pneumoniae* (formerly *D. pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K. pneumoniae*), *E. coli, Proteus mirabilis,* and *Serratia marcescens**.

Skin and Skin Structure Infections due to *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis, Streptococcus pyogenes, Streptococcus* species (excluding enterococci), *Escherichia coli, Klebsiella pneumoniae, Peptococcus niger**, *Peptostreptococcus* species.

Gynecologic Infections caused by *Staphylococcus aureus* (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis, Streptococcus* species (excluding enterococci), *Streptococcus agalactiae, E. coli, Proteus mirabilis, Neisseria gonorrhoeae,* Bacteroides species (excluding *B. distasonis, B. ovatus, B. thetaiotaomicron*), *Fusobacterium* species*, and gram-positive anaerobic cocci (including *Peptococcus niger* and *Peptostreptococcus* species).

Cefotetan, like other cephalosporins, has no activity against *Chlamydia trachomatis.* Therefore, when cephalosporins are used in the treatment of pelvic inflammatory disease, and *C. trachomatis* is one of the suspected pathogens, appropriate antichlamydial coverage should be added.

Intra-abdominal Infections caused by *E. coli, Klebsiella* species (including *K. pneumoniae*), *Streptococcus* species (excluding enterococci), *Bacteroides* species (excluding *B. distasonis, B. ovatus, B. thetaiotaomicron*) and *Clostridium* species*.

Bone and Joint Infections caused by *Staphylococcus aureus**.

*Efficacy for this organism in this organ system was studied in fewer than ten infections.

Specimens for bacteriological examination should be obtained in order to isolate and identify causative organisms and to determine their susceptibilities to cefotetan. Therapy may be instituted before results of susceptibility studies are known; however, once these results become available, the antibiotic treatment should be adjusted accordingly.

In cases of confirmed or suspected gram-positive or gram-negative sepsis or in patients with other serious infections in which the causative organism has not been identified, it is possible to use CEFOTAN concomitantly with an aminoglycoside. Cefotetan combinations with aminoglycosides have been shown to be synergistic *in vitro* against many Enterobacteriaceae and also some other gram-negative bacteria. The dosage recommended in the labeling of both antibiotics may be given and depends on the severity of the infection and the patient's condition.

NOTE: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycosidic antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

PROPHYLAXIS

The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (e.g., cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).

The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.

If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS

CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS

BEFORE THERAPY WITH CEFOTAN IS INSTITUTED, CAREFUL INQUIRY SHOULD BE MADE TO DETERMINE WHETHER THE PATIENT HAS HAD PREVIOUS HYPERSENSITIVITY REACTIONS TO CEFOTETAN DISODIUM, CEPHALOSPORINS, PENICILLINS, OR OTHER DRUGS. IF THIS PRODUCT IS TO BE GIVEN TO PENICILLIN-SENSITIVE PATIENTS, CAUTION SHOULD BE EXERCISED BECAUSE CROSS-HYPERSENSITIVITY AMONG BETA-LACTAM ANTIBIOTICS HAS BEEN CLEARLY DOCUMENTED AND MAY OCCUR IN UP TO 10% OF PATIENTS WITH A HISTORY OF PENICILLIN ALLERGY. IF AN ALLERGIC REACTION TO CEFOTAN OCCURS, DISCONTINUE THE DRUG. SERIOUS ACUTE HYPERSENSITIVITY REACTIONS MAY REQUIRE TREATMENT WITH EPINEPHRINE AND OTHER EMERGENCY MEASURES, INCLUDING OXYGEN, INTRAVENOUS FLUIDS, INTRAVENOUS ANTIHISTAMINES, CORTICOSTEROIDS, PRESSOR AMINES AND AIRWAY MANAGEMENT, AS CLINICALLY INDICATED.

Pseudomembranous colitis has been reported with nearly all antibacterial agents, including cefotetan, and may range from mild to life-threatening. Onset of pseudomembranous colitis symptoms may occur during or after antibiotic treatment or surgical prophylaxis. Therefore, it is important to consider this diagnosis in patients who present with diarrhea subsequent to the administration of antibacterial agents.

Treatment with antibacterial agents alters the normal flora of the colon and may permit overgrowth of clostridia. Studies indicate that a toxin produced by *Clostridium difficile* is a primary cause of "antibiotic-associated colitis."

After the diagnosis of pseudomembranous colitis has been established, therapeutic measures should be initiated. Mild cases of pseudomembranous colitis usually respond to discontinuation of the drug alone. In moderate to severe cases, consideration should be given to management with fluids and electrolytes, protein supplementation, and treatment with an oral antibacterial drug effective against *Clostridium difficile.*

In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity and, possibly, subsequent bleeding. Those at increased risk include patients with renal or hepatobiliary impairment or poor nutritional state, the elderly, and patients with cancer. Prothrombin time should be monitored and exogenous vitamin K administered as indicated.

PRECAUTIONS

General: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.

Information for Patients: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc.) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.

Drug Interactions: Although to date nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

Drug/Laboratory Test Interactions: The administration of CEFOTAN may result in a false-positive reaction for glucose in the urine using Clinitest®†, Benedict's solution, or Fehling's solution. It is recommended that glucose tests based on enzymatic glucose oxidase be used.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels by Jaffe reaction and produce false increases in the levels of creatinine reported.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approximately 8-16 times the usual adult human dose) on days 6-35 of life (thought to be developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approximately 2-4 times the usual human dose) only 1 of 10 treated animals was affected, and the degree of degeneration was mild.

Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.

Pregnancy: Teratogenic Effects. Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

In clinical studies, the following adverse effects were considered related to CEFOTAN therapy. Those appearing in italics have been reported during postmarketing experience.

Gastrointestinal symptoms occurred in 1.5% of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700); *pseudomembranous colitis.* Onset of pseudomembranous colitis symptoms may occur during or after antibiotic treatment or surgical prophylaxis. (See WARNINGS.)

Hematologic laboratory abnormalities occurred in 1.4% of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300); *agranulocytosis, hemolytic anemia, leukopenia, thrombocytopenia,* and *prolonged prothrombin time.*

Hepatic enzyme elevations occurred in 1.2% of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).

Hypersensitivity reactions were reported in 1.2% of patients and included rash (1 in 150) and itching (1 in 700); *anaphylactic reactions.*

Local effects were reported in less than 1.0% of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500).

Miscellaneous: *Fever*

In addition to the adverse reactions listed above which have been observed in patients treated with cefotetan, the following adverse reactions and altered laboratory tests have been reported for cephalosporin-class antibiotics: urticaria, pruritis, Stevens-Johnson syndrome, erythema multiforme, toxic epidermal necrolysis, vomiting, abdominal pain, colitis, superinfection, vaginitis including vaginal candidiasis, renal dysfunction, toxic nephropathy, hepatic dysfunction including cholestasis, aplastic anemia, hemorrhage, increased BUN, increased creatinine, elevated bilirubin, pancytopenia, and neutropenia.

Several cephalosporins have been implicated in triggering seizures, particularly in patients with renal impairment when the dosage was not reduced (see DOSAGE AND ADMINISTRATION and OVERDOSAGE). If seizures associated with drug therapy occur, the drug should be discontinued. Anticonvulsant therapy can be given if clinically indicated.

DOSAGE AND ADMINISTRATION
TREATMENT

The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Skin & Skin Structure		
Mild-Moderate[a]	2 grams	2 g every 24 hours IV 1 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6 grams[b]	3 g every 12 hours IV

[a] *K. pneumoniae* skin and skin structure infections should be treated with 1 or 2 grams every 12 hours IV or IM.

[b] Maximum daily dosage should not exceed 6 grams.

If *C. trachomatis* is a suspected pathogen in gynecologic infections, appropriate antichlamydial coverage should be added, since cefotetan has no activity against this organism.

PROPHYLAXIS

To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.

IMPAIRED RENAL FUNCTION

When renal function is impaired, a reduced dosage schedule must be employed. See FULL PRESCRIBING INFORMATION for a complete description.

NOTE: Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration whenever solution and container permit.

Term birth after midtrimester hysterotomy and selective delivery of an acardiac twin 33

Norman A. Ginsberg, MD, Michael Applebaum, MD, Steven A. Rabin, MD, Melissa A. Caffarelli, MS, Monika Kuuspalu, RT, RDMS, Jay L. Daskal, MD, Yury Verlinsky, PhD, Charles M. Strom, MD, PhD, and John J. Barton, MD

Chicago, Illinois

Midgestation hysterotomy to deliver an acardiac twin fetus is described with term delivery of its healthy "pump" twin; a report of acardius in a triplet pregnancy is also presented.

Idiopathic myelofibrosis in pregnancy: A case report and review of the literature 38

Udele B. Taylor, MD, Arlene D. Bardeguez, MD, Nidia Iglesias, MD, and Pedro Gascon, MD, PhD

Newark, New Jersey

A case of idiopathic myelofibrosis in pregnancy is reported and its management is discussed.

Oral contraceptive use and the incidence of cervical intraepithelial neoplasia 40

Inger T. Gram, MD, Maurizio Macaluso, MD, DrPH, and Helge Stalsberg, MD

Tromsö, Norway, and Birmingham, Alabama

A follow-up study of 6622 Norwegian women supports the hypothesis that the incidence of cervical intraepithelial neoplasia is increased by oral contraceptive use.

Calcium homeostasis in pregnant women receiving long-term magnesium sulfate therapy for preterm labor 45

Leon G. Smith, Jr., MD, Pamela A. Burns, RN, and Richard J. Schanler, MD

Houston, Texas

Long-term magnesium sulfate therapy in the last trimester of pregnancy resulted in changes in maternal calcium homeostasis and bone mineralization.

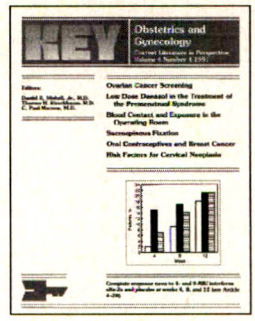
Nifedipine for treatment of preterm labor: A historic prospective study 52

Carolyn Murray, MD, MPH, Albert D. Haverkamp, MD, Miriam Orleans, PhD, Sally Berga, MD, PhD, and Denise Pecht, MD

Denver, Colorado

In 102 patients treated with nifedipine for preterm labor, maternal side effects were mild and no adverse fetal or neonatal effects were observed.

Nonimmune hydrops fetalis associated with maternal infection with syphilis 56



John R. Barton, MD, Edwin M. Thorpe, Jr., MD, David C. Shaver, MD, W. David Hager, MD, and Baha M. Sibai, MD

Lexington, Kentucky, and Memphis, Tennessee

Three cases of nonimmune hydrops fetalis in association with intrauterine infection with syphilis were diagnosed antenatally; an aggressive management resulted in survival of all neonates.

Suppression of 24-hour cholecystokinin secretion by oral contraceptives 58
Roger Karlsson, MD, Angelica Lindén, MD, PhD, and Bo von Schoultz, MD, PhD
Umeà and Stockholm, Sweden

Treatment with oral contraceptives caused a suppression of 24-hour cholecystokinin secretion, which could be related to side effects such as increased appetite and weight gain.

Delayed endometrial maturation induced by daily administration of the antiprogestin RU 486: A potential new contraceptive strategy 60
Marcelo C. Batista, MD, Tannia P. Cartledge, RN, Ann W. Zellmer, RN, Maria J. Merino, MD, Constantine Axiotis, MD, D. Lynn Loriaux, MD, PhD, and Lynnette K. Nieman, MD
Bethesda, Maryland

Daily administration of the antiprogestin RU 486 (1 mg/day) throughout the menstrual cycle delays endometrial maturation and may offer a novel strategy for human fertility control.

Antenatal tests of fetal welfare and development at age 2 years 66
Angela L. Todd, BA, Brian J. Trudinger, MD, Michael J. Cole, MB, and George H. Cooney, PhD
Westmead, New South Wales, Australia

In fetuses delivered electively before 34 weeks, an abnormal fetal heart rate rather than a Doppler result was more strongly associated with poorer development at 2 years, but all fetuses performed less well than a control group delivered spontaneously before 34 weeks.

Retrospective maternal mortality case ascertainment in West Virginia, 1985 to 1989 72
Timothy D. Dye, MA, MPA, MS, Howard Gordon, MD, Berel Held, MD, Nancy J. Tolliver, MSIR, and Alan P. Holmes, MBA
Charleston, Morgantown, and Huntington, West Virginia

Increases in maternal mortality highlight the importance of amplified surveillance and reporting of maternal deaths and the need for enhanced case review of potential maternal deaths.

Laparoscopic diagnosis and repair of spigelian hernia: Report of a case and technique 77
James E. Carter, MD, PhD, and Craig Mizes, MD
Mission Viejo, California

The procedures for laparoscopic visualization, dissection, and repair of acquired spigelian hernia are outlined.

Oligohydramnios and megacolon in a fetus with vesicorectal fistula and anal-urethral atresia: A case report 79
Mordechai Hallak, MD, Alexander A. Reiter, MD, Leon G. Smith, Jr., MD, Gary A. Dildy III, MD, and Milton J. Finegold, MD
Houston, Texas

Congenital diversion of urine into the colon of a fetus with vesicorectal fistula and urethral-anal atresia produced an abdominal mass and oligohydramnios.

These days, this isn't all you have to deliver.

The demands placed on physicians are growing, and changing, as never before.

That's why Caremark - an affiliate of Baxter Healthcare Corporation - has created Women's Health.

We offer comprehensive services to support both your practice, and your patients, with a special focus on the management of high risk pregnancies.

Our sophisticated yet simple First Activity™ Monitor lets you oversee high risk pregnancies 24 hours a day. Your patients collect data on uterine activity and other physiological indicators at home, transmitting it to our perinatal nurses for immediate review. So you receive timely information, allowing you to prescribe the best treatment, at the right time. (Use of the device to detect pre-term labor, prior to 36 week gestation, is still considered investigational.)

What's more, with skilled Caremark pharmacists, perinatal and IV nurses available day and night, you can be sure your patients will get the quality of care you prescribe.

For more information, call 1-800-423-1411. We can help you deliver more.

Pathways to hysterectomy: Insights from longitudinal twin research 82
Susan A. Treloar, MSW, Nicholas G. Martin, PhD, Lorraine Dennerstein, PhD, Beverley Raphael, MD, and Andrew C. Heath, DPhil
Brisbane, Queensland, and Melbourne, Victoria, Australia

Analysis of hysterectomy and its covariates, in a two-wave Australian twin study, suggests strong genetic effects on hysterectomy.

Maternal and fetal hemodynamic effects of autologous blood donation during pregnancy 89
Sabine Droste, MD, Tanya Sorensen, MD, Thomas Price, MD, Merlin Sayers, MD, Thomas Benedetti, MD, Thomas Easterling, MD, and Susan Hendricks, MD
Madison, Wisconsin, and Seattle, Washington

The magnitude of hemodynamic change after the acute loss of 1 U of blood was found to be less than that associated with ordinary orthostasis.

First-trimester diagnosis of cystic hygroma—Course and outcome 94
Rieteke M. van Zalen-Sprock, MD, John M.G. van Vugt, MD, PhD, and Herman P. van Geijn, MD, PhD
Amsterdam, The Netherlands

This article describes the outcome of 22 fetuses with cystic hygroma detected in the first trimester of pregnancy with transvaginal ultrasonographic examination.

Baking powder pica mimicking preeclampsia 98
John R. Barton, MD, Caroline A. Riely, MD, and Baha M. Sibai, MD
Memphis, Tennessee

Baking powder pica during pregnancy was associated with maternal hypertension, hypokalemia, and elevated values of liver function tests.

Presacral neurectomy for the treatment of pelvic pain associated with endometriosis: A controlled study 100
Giovanni Battista Candiani, MD, Luigi Fedele, MD, Paolo Vercellini, MD, Stefano Bianchi, MD, and Giuliana Di Nola, MD
Milan, Italy

The addition of presacral neurectomy to conservative surgery for moderate or severe endometriosis did not reduce pelvic pain more than did conservative surgery alone.

Self-administered home cervicovaginal lavage: A novel tool for the clinical-epidemiologic investigation of genital human papillomavirus infections 104
Ellen A.B. Morrison, MD, Gary L. Goldberg, MD, Robert J. Hagan, MS, Anna S. Kadish, MD, and Robert D. Burk, MD
Bronx, New York

Human papillomavirus detection by polymerase chain reaction and Southern blot on samples from physician-administered or self-administered cervicovaginal lavage yielded similar results.

Cold therapy in the management of postoperative cesarean section pain 108
Soheil Amin-Hanjani, MD, Joseph Corcoran, DO, and Ashwin Chatwani, MD
Philadelphia, Pennsylvania

Use of cold therapy for postoperative cesarean section pain is presented.

Cyclooxygenase products do not modulate angiotensin II–induced contractions of human chorionic plate arteries 110
Grigory Sorokin, BS, Nancy M. Grant, BS, Brent M. Egan, MD, and Julian H. Lombard, PhD
Milwaukee, Wisconsin

Angiotensin II–induced contractions of human chorionic plate arteries are unaffected by indomethacin, and exogenous arachidonic acid produces an indomethacin-sensitive contraction of the vessels.

Perihepatic adhesions: Not necessarily pathognomonic of pelvic infection 115
Soheil Amin-Hanjani, MD, Thomas Neely, MD, and Ashwin Chatwani, MD
Philadelphia, Pennsylvania

Perihepatic adhesions were observed by laparoscopy in 17% of otherwise normal women undergoing interval sterilization.

Prophylactic amnioinfusion improves outcome of pregnancy complicated by thick meconium and oligohydramnios 117
Charles J. Macri, MD, CDR, MC, USN, David B. Schrimmer, MD, Anna Leung, MD, Jeffrey S. Greenspoon, MD, and Richard H. Paul, MD
Los Angeles, California

Amnioinfusion was demonstrated to decrease significantly the rates of cesarean delivery and meconium aspiration syndrome in pregnancies complicated by thick meconium and oligohydramnios.

Spontaneous ovarian hyperstimulation syndrome concomitant with spontaneous pregnancy in a woman with polycystic ovary disease 122
Yaron Zalel, MD, Zvi Katz, MD, Benjamin Caspi, MD, Herzel Ben-Hur, MD, Rami Dgani, MD, and Vaclav Insler, MD
Rehovot, Israel

A case of spontaneous hyperstimulation in association with spontaneous pregnancy is presented; the possible role of polycystic ovary disease in hyperstimulation of the ovary is discussed.

Screening for Down syndrome with the femur length/biparietal diameter ratio: A new twist of the data 124
Lawrence D. Platt, MD, Arnold L. Medearis, MD, Dru E. Carlson, MD, Rena E. Falk, MD, Greggory R. DeVore, MD, Janet Horenstein, MD, and Catherine A. Walla, RN, MA, MN
Los Angeles, California

Although data suggest that biometric measurements may be advantageous in screening for Down syndrome, larger numbers are required before their introduction into clinical practice.

Rupture of uterine scar with extensive maternal bladder laceration after cocaine abuse 129

Chaur-Dong Hsu, MD, MPH, Serena Chen, MD, Terry I. Feng, MD, MPH, and Timothy R.B. Johnson, MD

Baltimore, Maryland

A patient is described with cocaine abuse and rupture of a uterine scar, as well as extensive maternal bladder laceration.

Comparison of the efficacy of different local anesthetics and techniques of local anesthesia in therapeutic abortions 131

Ellen R. Wiebe, MD

Vancouver, British Columbia, Canada

During therapeutic abortions, carbonated lidocaine reduced pain scores by 8% compared with plain lidocaine; deep injections of lidocaine reduced pain scores by 25% compared with regular injections.

Simultaneous ovarian and intrauterine pregnancy: Case report 134

Anna Bernabei, MD, Giuseppe Morgante, MD, Massimo Mazzini, MD, Elisabetta Guerrini, MD, Antonio Fava, MD, and Secondo Danero, MD

Siena, Italy

A case of simultaneous ovarian and intrauterine pregnancy was successfully treated.

Antibodies to *Chlamydia trachomatis* in sera of women with recurrent spontaneous abortions 135

Steven S. Witkin, PhD, and William J. Ledger, MD

New York, New York

Among women with no history of chlamydial infection, the presence of antibodies to *Chlamydia trachomatis* was associated with recurrent spontaneous abortion.

Randomized, double-blind study of cefotetan and cefoxitin in post–cesarean section endometritis 139

Rob Roy MacGregor, MD, Amy L. Graziani, PharmD, and Philip Samuels, MD

Philadelphia, Pennsylvania

Cefotetan and cefoxitin were found to be equally efficacious and safe in the first double-blind study of the drugs in post–cesarean section endometritis.

Interactions between intrauterine contraceptive device use and breast-feeding status at time of intrauterine contraceptive device insertion: Analysis of TCu-380A acceptors in developing countries 144

Gaston Farr, MA, and Roberto Rivera, MD

Research Triangle Park, North Carolina

Breast-feeding among intrauterine contraceptive device users was associated with fewer insertion-related complaints and lower removal rates for bleeding and pain.

Survival and disease progression in human immunodeficiency virus–infected women after an index delivery 152
D. Jay Gloeb, DO, Shenghan Lai, PhD, JoNell Efantis, RN, ARNP, and Mary Jo O'Sullivan, MD
Miami, Florida

The majority of 103 human immunodeficiency virus antibody–positive pregnant women monitored prospectively were alive 3 years later, but lymphadenopathy syndrome at the index delivery or herpes genitalis during pregnancy was significantly associated with a subsequent diagnosis of acquired immunodeficiency syndrome.

Enhanced follicle regulatory protein levels accompany reinitiation of ovulatory function after parturition 158
Barry D. Albertson, PhD, Kathy E. Rodgers, PhD, Thomas P. Tomai, MS, Kathy Nolan-Watson, MD, Michael J. Zinaman, MD, and Gere S. DiZerega, MD
Washington, D.C., and Los Angeles, California

Increased urinary follicle regulatory protein levels are associated with the appearance of a functional corpus luteum in breast-feeding, postpartum women.

Immunolocalization of the vasoconstrictor endothelin in human endometrium during the menstrual cycle and in umbilical cord at birth 163
Lois A. Salamonsen, PhD, Anna R. Butt, Anne M. Macpherson, BSc(Hons.), Peter A.W. Rogers, PhD, and Jock K. Findlay, PhD
Clayton, Victoria, Australia

Immunoreactive endothelin was detected in endometrial stroma throughout the menstrual cycle, in endometrial epithelium during the secretory phase, and in umbilical endothelial and amniotic cells.

Reduced platelet tritium-labeled imipramine binding sites in women with premenstrual syndrome 168
John F. Steege, MD, Anna L. Stout, PhD, David L. Knight, BS, and Charles B. Nemeroff, MD, PhD
Durham, North Carolina

Women with premenstrual syndrome have tritium-labeled imipramine binding levels similar to those seen in women with depression.

The development of ultradian rhythms in the human fetus 172
Mary Pillai, MB, David K. James, MD, and Michael Parker, MB
Bristol, Canada

Emergence of the cyclic distribution of fetal activity and the development of linkage of conditions of a number of fetal activities are described.

Contents

BASIC SCIENCE SECTION

Effect of calcitonin gene-related peptide on the uterine vasculature of the nonpregnant ewe 178

Daseng Yang, MD, George A. Van Buren, MD, and Kenneth E. Clark, PhD

Cincinnati, Ohio

Calcitonin gene-related peptide was 10 times more potent than prostacyclin as a uterine vasodilator in the nonpregnant ewe.

An ultrastructural study of the developing urogenital tract in early human fetuses 185

W. Dwayne Lawrence, MD, Diana Whitaker, MS, Hoshiki Sugimura, MD, Gerald R. Cunha, PhD, G. Richard Dickersin, MD, and Stanley J. Robboy, MD

Detroit, Michigan, Philadelphia, Pennsylvania, San Francisco, California, Boston, Massachusetts, Newark, New Jersey, and Mie-Kan, Japan

The mesonephric (wolffian) and paramesonephric (müllerian) ducts have separate origins and both show evidence of a role for extensive epithelial-stromal interaction in their cytodifferentiation.

Activation of protein kinase C stimulates collagenase production by cultured cells of the cervix of the pregnant guinea pig 194

Mohammad R. Rajabi, MD, PhD, Samuel Solomon, PhD, and A. Robin Poole, PhD

Montreal, Quebec, Canada

Activation of protein kinase C results in stimulation of collagenase production in cervical cell cultures of the pregnant guinea pig.

Hydrogen peroxide and reoxygenation cause prostaglandin-mediated contraction of human placental arteries and veins 201

Hatim A. Omar, MD, Reinaldo Figueroa, MD, Rawhi A. Omar, MD, PhD, Nergesh Tejani, MD, and Michael S. Wolin, PhD

Valhalla, New York, and Morgantown, West Virginia

Increases in oxygen tension appear to produce contraction of placental arteries and veins by generation of hydrogen peroxide, a stimulus for the production of prostaglandins.

Inhibitory effect of medroxyprogesterone acetate on angiogenesis induced by human endometrial cancer 207

Hiroaki Jikihara, MD, Nobuyuki Terada, MD, PhD, Reiko Yamamoto, CT(IAC), Yoshinobu Nishikawa, MD, Osamu Tanizawa, MD, PhD, Keishi Matsumoto, MD, PhD, and Naoki Terakawa, MD, PhD

Osaka and Yonago, Japan

Inhibition of angiogenesis may be one of the mechanisms by which medroxyprogesterone acetate inhibits the growth of endometrial adenocarcinoma.

Changes in expression of the cyclooxygenase gene in human fetal membranes and placenta with labor 212
Phillip R. Bennett, BSc, MD, Deborah J. Henderson, BSc, and Gudrun E. Moore, BA, PhD
London, England

Human amnion, chorion-decidua, and trophoblast express the gene for cyclooxygenase at low levels during pregnancy, with a large increase in expression in amnion and trophoblast in association with labor.

A novel change in cytologic localization of human chorionic gonadotropin and human placental lactogen in first-trimester placenta in the course of gestation 217
Takeshi Maruo, MD, Cecilia A. Ladines-Llave, MD, Hiroya Matsuo, MD, Augusto S. Manalo, MD, and Matsuto Mochizuki, MD
Kobe, Japan, and Manila, Philippines

During the course of early development of the placenta, there is a change in cytologic localization of human chorionic gonadotropin and human placental lactogen from cytotrophoblast to syncytiotrophoblast around the sixth week of gestation.

Transforming growth factor-β opposes the stimulatory effects of interleukin-1 and tumor necrosis factor on amnion cell prostaglandin E_2 production: Implication for preterm labor 222
Kristina Bry, MD, and Mikko Hallman, MD
Irvine, California, and Helsinki, Finland

We propose that transforming growth factor-β maintains pregnancy in the face of labor-promoting cytokines.

Mutations of the Ki-*ras* oncogene in endometrial carcinoma 227
Diane Ignar-Trowbridge, PhD, John I. Risinger, MS, Georgette A. Dent, MD, Matthew Kohler, MD, Andrew Berchuck, MD, John A. McLachlan, PhD, and Jeff Boyd, PhD
Research Triangle Park, Chapel Hill, and Durham, North Carolina

A specific activating point mutation of the Ki-*ras* oncogene was detected in 10% of endometrial carcinomas.

Effect of maternal oxygen administration on fetal oxygenation during graded reduction of umbilical or uterine blood flow in fetal sheep 233
Rene P. Paulick, MD, Rebecka L. Meyers, MD, and Abraham M. Rudolph, MD
San Francisco, California

Administration of oxygen to the ewe significantly improved fetal oxygenation associated with reduced umbilical blood flow, particularly when uterine blood flow was reduced.

Convulsions in pregnancy in related gorillas 240
James G. Thornton, MD, and Joseph L. Onwude, MB
Leeds, England

While breeding in captivity both a gorilla and its grandmother had convulsions, which may have been eclampsia, during pregnancy.

Contents

Messenger ribonucleic acid for transforming growth factor-α, but not for epidermal growth factor, is expressed in fetal and neonatal mouse brain 242

John Yeh, MD, Kenneth M. Rosen, PhD, and Lydia Villa-Komaroff, PhD
Boston, Massachusetts

Reverse transcription followed by polymerase chain reaction, a highly sensitive technique, demonstrated fetal and neonatal mouse brain transforming growth factor-α gene expression for the first time.

Cardiac electromechanical dissociation in the hypoxic fetal sheep may have clinical implications 246

Reuven M. Lewinsky, MD, Lawrence W. Oppenheimer, MB, Robert J. Morrow, MD, S. Lee Adamson, PhD, Dan Farine, MD, and J.W. Knox Ritchie, MD
Toronto, Ontario, Canada

An electrocardiographic waveform persisted after mechanical asystole in eight fetal sheep dying of hypoxic acidemia, suggesting that electromechanical dissociation may be an important event in some intrapartum deaths.

SYMPOSIUM ON THE PATHOPHYSIOLOGY OF INFERTILITY ASSOCIATED WITH ENDOMETRIOSIS

Introductory remarks 250

Yuji Taketani, MD, PhD, Naoki Terakawa, MD, PhD, and Hiroshi Hoshiai, MD, PhD
Tokyo, Yonago, and Osaka, Japan

The fetus as an allograft: Immunobiologic role of human trophoblasts for fetal survival 251

Fumitaka Saji, MD, DMSci, Noboru Matsuzaki, MD, DMSci, Chihiro Azuma, MD, DMSci, Masayasu Koyama, MD, DMSci, Kazutomo Ohashi, MD, DMSci, and Osamu Tanizawa, MD, DMSci
Osaka, Japan

Immunologic and molecular biologic studies indicate the important role of human trophoblasts for the survival of the fetoplacental allograft during pregnancy.

Suppression of natural killer cell activity by sera from patients with endometriosis 257

Hideharu Kanzaki, MD, Huei-Sheng Wang, MD, Masatoshi Kariya, MD, and Takahide Mori, MD
Kyoto, Japan

Sera from patients with endometriosis suppressed natural killer cell activity in vitro in a dose- and time-dependent manner.

(Contents continued on page 18A)

Contents continued from page 17A

Significance of peritoneal macrophages on fertility in mice 261
Naohiko Umesaki, MD, PhD, Satoshi Uda, MD, Masami Kawabata, MD, PhD, and Sachio Ogita, MD, PhD
Osaka, Japan

In our experimental model increased macrophage infiltration of the peritoneal cavity resulted in reduced fecundity.

Comparison of cytokine levels and embryo toxicity in peritoneal fluid in infertile women with untreated or treated endometriosis 265
Yuji Taketani, MD, PhD, Tong-Ming Kuo, MD, PhD, and Masahiko Mizuno, MD, PhD
Tokyo, Japan

We present evidence for the decrease of cytokine levels and concomitant elimination of embryo toxicity in peritoneal fluid of women with endometriosis after medical treatment.

Luteinized unruptured follicle in the early stages of endometriosis as a cause of unexplained infertility 271
Yasuyuki Mio, MD, PhD, Toshiko Toda, MD, PhD, Tasuku Harada, MD, PhD, and Naoki Terakawa, MD, PhD
Yonago, Japan

Luteinized unruptured follicle frequently occurs in patients with early stages of endometriosis and may be one of the causes of endometriosis-associated infertility.

Luteal function in infertile patients with endometriosis 274
Koji Kusuhara, MD
Tokyo, Japan

The luteal function was investigated in infertile patients with or without endometriosis; the results indicate that luteal function defects are not directly related to endometriosis-associated infertility.

The impact of endometriosis on the reproductive outcome of infertile patients 278
Masato Inoue, MD, DMSci, Yoshimune Kobayashi, MD, DMSci, Ikuko Honda, MD, Hideo Awaji, MD, and Akikazu Fujii, MD, DMSci
Kanagawa, Japan

The presence of endometriosis did not affect the subsequent conception rates in infertile patients.

Mechanisms involved in the pituitary desensitization induced by gonadotropin-releasing hormone agonists 283
Tsuguo Uemura, MD, PhD, Takashi Yanagisawa, MD, Kazuhiro Shirasu, MD, Akemi Matsuyama, MD, PhD, and Hiroshi Minaguchi, MD, PhD
Yokohama, Japan

Gonadotropin-releasing hormone agonists reduced the binding of gonadotropin-releasing hormone, luteinizing hormone release, and luteinizing hormone-β messenger ribonucleic acid and presumably altered the molecular structure of released luteinizing hormone; these effects may be involved in gonadal suppression.

Make researching easier with the Ten-Year Cumulative Index (1978-1987) to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY

The Ten-Year Cumulative Index is a complete guide to more than 30,000 pages of original articles, case reports, letters, and editorials published in the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY from 1978 through 1987 (volumes 130 to 157). Numbering more than 800 pages, the Cumulative Index includes both a subject and an author index. This hard-cover volume is $64.50 ($69.00 international). Prices include shipping. *Payment must accompany all orders and must be in U.S. funds, drawn on a U.S. bank.*

Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318 USA; phone (314) 453-4394. In the U.S., call toll-free: 1-800-325-4177, ext. 4394. Please allow six weeks for delivery.

The JOURNAL is abstracted and/or indexed in *Index Medicus, Science Citation Index, Current Contents/Clinical Medicine, Current Contents/Life Sciences, Excerpta Medica, BRS Colleague,* and MEDLINE.

Authorization to photocopy items for internal or personal use is granted by Mosby–Year Book, Inc., for libraries and other users registered with the Copyright Clearance Center (CCC) Transactional Reporting Service, provided that 10¢ per page per copy is paid directly to CCC, 27 Congress St., Salem, MA 01970; phone (508)744-3350. The U.S. Government retains a nonexclusive, royalty-free license in and to any copyright on articles authored by government employees. 0002-9378/92 $00.00 + .10.

You think it's good medicine. She thinks it's wonderful.

Thanks to you and Premarin®, she could make these years the best years of her life

Hot flashes–Now part of the past for millions of women
Premarin® can dramatically reduce the incidence of hot flashes, night sweats, and related sleep disturbances.

Osteoporosis–No longer part of the future for many women
Premarin® is the first estrogen product proven to prevent postmenopausal osteoporosis in women at risk. And it's the *only* estrogen product proven in studies to reduce the risk of osteoporosis-related fractures by as much as 62%.[1]

Contraindications

Estrogens should not be used in women (or men) with any of the following conditions: known or suspected 1) pregnancy, 2) breast cancer, 3) estrogen-dependent neoplasia, 4) undiagnosed abnormal genital bleeding, 5) active thrombophlebitis or thromboembolic disorders.

Note: Estrogens have been reported to increase the risk of endometrial carcinoma in postmenopausal women.

Nothing else is

PREMARIN®

(conjugated estrogens tablets)

The appearance of this tablet is a trademark of Wyeth-Ayerst Laboratories.

Please see brief summary of prescribing information on next page.

BRIEF SUMMARY *(FOR FULL PRESCRIBING INFORMATION AND PATIENT INFORMATION, SEE PACKAGE CIRCULARS.)*

PREMARIN® Brand of conjugated estrogens tablets, USP
PREMARIN® Brand of conjugated estrogens Vaginal Cream, in a nonliquefying base

1. ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA. Close clinical surveillance of all women taking estrogens is important. Adequate diagnostic measures including endometrial sampling when indicated should be undertaken to rule out malignancy in all cases of undiagnosed persistent or recurring abnormal vaginal bleeding. There is currently no evidence that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.
2. ESTROGENS SHOULD NOT BE USED DURING PREGNANCY.
Estrogen therapy during pregnancy is associated with an increased risk of congenital defects in the reproductive organs of the male and female fetus, an increased risk of vaginal adenosis, squamous-cell dysplasia of the uterine cervix, and vaginal cancer in the female later in life. The 1985 DES Task Force concluded that women who used DES during their pregnancies may subsequently experience an increased risk of breast cancer. However, a causal relationship is still unproven, and the observed level of risk is similar to that for a number of other breast cancer risk factors.
There is no indication for estrogen therapy during pregnancy. Estrogens are ineffective for the prevention or treatment of threatened or habitual abortion.

DESCRIPTION: PREMARIN (conjugated estrogens, USP) contains a mixture of estrogens, obtained exclusively from natural sources, blended to represent the average composition of material derived from pregnant mares' urine. It contains estrone, equilin, and 17α-dihydroequilin, together with smaller amounts of 17α-estradiol, equilenin, and 17α-dihydroequilenin as salts of their sulfate esters. Tablets are available in 0.3 mg, 0.625 mg, 0.9 mg, 1.25 mg, and 2.5 mg strengths of conjugated estrogens. Cream is available as 0.625 mg conjugated estrogens per gram.

INDICATIONS AND USAGE: Moderate-to-severe vasomotor symptoms associated with the menopause. (There is no evidence that estrogens are effective for nervous symptoms or depression which might occur during menopause and they should not be used to treat these conditions.) Prevention and management of osteoporosis (abnormally low bone mass). Atrophic vaginitis. Atrophic urethritis. Hypoestrogenism due to hypogonadism, castration or primary ovarian failure.

PREMARIN (conjugated estrogens) Vaginal Cream is indicated in the treatment of atrophic vaginitis and kraurosis vulvae.

PREMARIN HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

CONTRAINDICATIONS: Estrogens should not be used in women (or men) with any of the following conditions: 1. Known or suspected pregnancy (see Boxed Warning). 2. Known or suspected cancer of the breast except in appropriately selected patients being treated for metastatic disease. 3. Known or suspected estrogen-dependent neoplasia. 4. Undiagnosed abnormal genital bleeding. 5. Active thrombophlebitis or thromboembolic disorders. 6. Estrogen replacement therapy has not been reported to increase the risk of thrombophlebitis and/or thromboembolic disease. However, there is insufficient information regarding women who have had previous thromboembolic disease.

PREMARIN Tablets and Vaginal Cream should not be used in patients hypersensitive to their ingredients.

WARNINGS: Some studies suggest a possible increased incidence of breast cancer in women taking higher doses of estrogen for prolonged time periods. The majority of studies have not shown an association with usual estrogen replacement doses. Endometrial cancer risk among estrogen users was about 4-fold or greater than in non-users, and appears dependent on treatment duration and estrogen dose. In patients on combined estrogen-progestin therapy, this risk appears to be decreased. (See PRECAUTIONS below.)

Estrogen therapy during pregnancy is associated with an increased risk of fetal congenital reproductive tract disorders.

A 2.5-fold increase in the risk of surgically confirmed gall bladder disease in women receiving postmenopausal estrogens has been reported.

Large doses of estrogen such as those used to treat prostate and breast cancer have been shown to increase the risk of non-fatal myocardial infarction, pulmonary embolism, and thrombophlebitis in men. This cannot necessarily be extrapolated to women. However, to avoid theoretical cardiovascular risk caused by high estrogen doses, the doses for estrogen replacement therapy should not exceed the recommended dose.

Blood pressure should be monitored with estrogen use, especially if high doses are used.

Estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases.

PRECAUTIONS: The addition of a progestin for 7 or more days of a cycle of estrogen administration reportedly lowers the incidence of endometrial hyperplasia. Studies of endometrium suggest that 10 to 13 days of progestin are needed to provide maximal endometrial maturation and elimination of hyperplastic changes. Additional risks, such as adverse effects on carbohydrate and lipid metabolism, may be associated with the inclusion of progestin in estrogen replacement regimens. The choice of progestin and dosage may be important in minimizing these adverse effects.

Physical examination and a complete medical and family history should be taken prior to the initiation of any estrogen therapy with special reference to blood pressure, breasts, abdomen, and pelvic organs, and should include a Papanicolaou smear. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination being performed. Conditions influenced by fluid retention, such as asthma, epilepsy, migraine, and cardiac or renal dysfunction, require careful observation. Certain patients may develop manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding and mastodynia. Pre-existing uterine leiomyomata may increase in size during estrogen use. Estrogens should be used with care in patients with impaired liver function, renal insufficiency, or metabolic bone diseases associated with hypercalcemia.

The following drug/laboratory test interactions have been reported, some only with estrogen-progestin combinations (oral contraceptives):

1. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.
2. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by T_4 levels determined by column or by radioimmunoassay. Free T_3 resin uptake is decreased, reflecting the elevated TBG; free T_4 concentration is unaltered.
3. Impaired glucose tolerance.
4. Reduced response to metyrapone test.
5. Reduced serum folate concentration.

MUTAGENESIS AND CARCINOGENESIS: Long-term, continuous administration of natural and synthetic estrogens in certain animal species increases the frequency of carcinomas of the breast, cervix, vagina, and liver.

PREGNANCY CATEGORY X: Estrogens should not be used during pregnancy. See **CONTRAINDICATIONS** and Boxed Warning.

NURSING MOTHERS: As a general principle, the administration of any drug to nursing mothers should be done only when clearly necessary since many drugs are excreted in human milk.

ADVERSE REACTIONS: The following have been reported with estrogenic therapy: changes in vaginal bleeding pattern and abnormal withdrawal bleeding or flow, breakthrough bleeding, spotting, increase in size of uterine fibromyomata, vaginal candidiasis, change in amount of cervical secretion; tenderness or enlargement of breasts; nausea, vomiting, abdominal cramps, bloating, cholestatic jaundice; chloasma or melasma that may persist when drug is discontinued, erythema multiforme, erythema nodosum, hemorrhagic eruption, loss of scalp hair, hirsutism; steepening of corneal curvature, intolerance to contact lenses; headache, migraine, dizziness, mental depression, chorea; increase or decrease in weight; reduced carbohydrate tolerance; aggravation of porphyria; edema; changes in libido.

ACUTE OVERDOSAGE: May cause nausea and vomiting.

DOSAGE AND ADMINISTRATION:

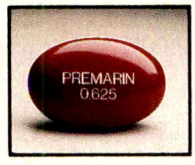
PREMARIN® Brand of conjugated estrogens tablets, USP

1. *Given cyclically for short-term use only.* For treatment of moderate-to-severe vasomotor symptoms, atrophic vaginitis, or atrophic urethritis associated with the menopause (0.3 mg to 1.25 mg or more daily). The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible. Administration should be cyclic (eg, three weeks on and one week off). Attempts to discontinue or taper medication should be made at three- to six-month intervals.
2. *Given cyclically:* Hypoestrogenism. Osteoporosis.
Hypoestrogenism due to: Female hypogonadism—2.5 mg to 7.5 mg daily in divided doses for 20 days followed by 10 day rest period. If bleeding does not occur by the end of this period, the same dosage schedule is repeated. Female castration or primary ovarian failure—1.25 mg daily, cyclically. Adjust upward or downward according to response of the patient. For maintenance, adjust dosage to lowest level that will provide effective control.
Osteoporosis—0.625 mg daily. Administration should be cyclic (eg, three weeks on and one week off).

PREMARIN® Brand of conjugated estrogens Vaginal Cream

Given cyclically for short-term use only. For treatment of atrophic vaginitis or kraurosis vulvae.

The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible.



Attempts to discontinue or taper medication should be made at three- to six-month intervals.

Usual dosage range: 2 g to 4 g daily, intravaginally, depending on the severity of the condition.

Patients with an intact uterus who are treated with either PREMARIN Tablets or Vaginal Cream should be monitored for signs of endometrial cancer and appropriate measures taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

Revised August 21, 1989

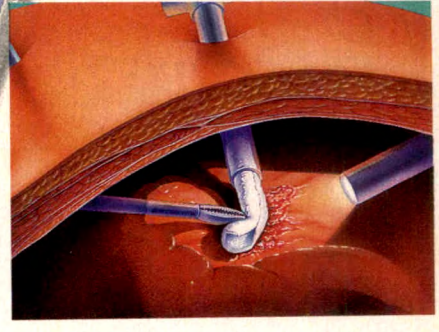
NEW from MedChem Products

Endo-Avitene™
Microfibrillar Collagen Hemostat in an Endoscopic Delivery System.

Avitene® Microfibrillar Collagen Hemostat (MCH) is now packaged ready for use in a unique delivery system designed for endoscopic procedures. This 100% collagen topical hemostat:

- eliminates risk of thermal damage.
- adheres tenaciously to the bleeding site.
- allows for the easy removal of excess by irrigation and suction.
- is effective in controlling delayed bleeding.
- is absorbable.



The Endo-Avitene device makes delivery and application of Avitene MCH to the bleeding site easy. Simply insert the delivery system through a 10 mm trocar sheath and deliver Avitene MCH directly to the bleeding site. Avitene MCH is positioned using a unique blunt plunger tip that can be used to apply pressure during placement.

MCH potentiates the clotting mechanism by attracting platelets.

We control bleeding. We reduce risk. And we deliver.

Contact us to arrange a demonstration. We'll supply the Endo-Avitene device free of charge. Call us today, and we'll deliver: 1-800-451-4716 (in Massachusetts, 617- 938-9328).

Endo-Avitene, for use in endoscopic procedures.

Foundation Congress of the EUROPEAN SOCIETY FOR GYNECOLOGI AND OBSTETRIC INVESTIGATION (E.S.G.O.I.)

Madonna di Campiglio (Italian Dolomites, Trentino, Italy February 7 - 14, 1993

Founders: Pedro N. Barri Raguè (Barcelona, Spain), **Jean Cohen** (Paris, France), **Tom K.A.B. Esl** (Nijmegen, The Netherlands), **Andrea R. Genazzani** (Modena, Italy), **Lars Hamberger** (Götebc Sweden), **Joseph G. Schenker** (Jerusalem, Israel), **Hermann P.G. Schneider** (Münster, Germa **Markku Seppälä** (Helsinki, Finland), **John Studd** (London, United Kingdom).

The goal of the E.S.G.O.I. is to put more emphasis to investigations in both basic and clinical aspects of stetrics and Gynecology as well as arranging - every two years - a common "forum" for debates on perimental, pharmacological, technological, molecular, surgical and other ongoing researches in our cipline.

The ESGOI's Foundation Congress will be held in **Madonna di Campiglio,** in the magnificent scenery the Italian Dolomites, and organized with Plenary Sessions, Minisymposia, Slide and Poster Sessions. Scientific Committee's efforts will be directed to involve in the final program the most updated resea groups as well as a large number of contributions originating from the various European Departments Obstetrics and Gynecology.

A Preliminary Programme containing the list of Special Lectures, Plenary Sessions and Forums will mailed upon request. The list of the proposed topics for minisymposia, slide and poster sessions is follows:

- gynecological oncology
- infective diseases
- gynecological endocrinology
- reproductive medicine
- fetal and perinatal medicine
- obstetric care
- menopause
- senology
- immunology
- molecular biology
- assisted procreation
- endoscopic surgery
- new surgical techniques
- oncogenes and carcinogenesis
- urogynecology
- psychobiology in Obst/Gynec
- contraception
- sexuology
- anesthesia and analgesia
- chemotherapy
- sexually transmitted diseases
- ultrasound and color doppler

Deadline for abstract submission will be **November 30, 1992.** The text of the abstract should be typed bond paper, single spacing within a frame (size: 16 cm/6.4 inches width - 12 cm/4.8 inches height) indic ing: title, authors, affiliation and text.

For further scientific information and abstract submission please contact:

Prof. Andrea R. Genazzani

INFORMATION FOR AUTHORS

Editorial policies

The requirements for manuscripts submitted to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors (N Engl J Med 1991;324:424-8). Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL.

Manuscript submission. Manuscripts should be submitted to one of the two Editors in Chief as follows:

1. **Dr. Zuspan**—manuscripts from the eastern and southeastern United States and from England, Israel, and Italy, manuscripts written for Clinical Opinion and Current Development, Letters to the Editors, and all manuscripts presented before one of the official sponsoring societies, except the Society for Gynecologic Investigation. *Manuscripts from The Society of Perinatal Obstetricians should be submitted to Dr. J. Peter Van Dorsten, P.O. Box 34, MCV Station, Richmond, VA 23298.*
2. **Dr. Quilligan**—manuscripts from states west of Pennsylvania, West Virginia, Kentucky, Tennessee, and Mississippi; manuscripts from Hawaii, Alaska, Canada, and abroad (except England, Israel, and Italy). Dr. Quilligan is responsible for manuscripts from the Society for Gynecologic Investigation. *Manuscripts from the Society for Gynecologic Investigation should be submitted to Dr. Roger A. Lobo, Women's Hospital, 1240 North Mission Road, Room 1M2, Los Angeles, CA 90033.*

Author's suggested reviewers. When authors submit their manuscripts, they must provide the names and addresses of at least three reviewers for consideration by the Editors.

Copyright statement. The specified copyright statement that follows the Information for Authors in each issue of the JOURNAL must be completed, signed by all authors, and submitted with the manuscript. If not completed in full, it will be returned to the author for completion. The copyright statement and checklist form may be torn from the JOURNAL or photocopied for submission.

Checklist. The checklist that appears with the copyright statement in each issue of the JOURNAL must be fully completed by the author(s) and sent with each submitted manuscript. A more complete description of each item that must be checked is provided under the appropriate heading in the Information for Authors, which is published in each issue of the JOURNAL. *If the checklist is not completed in full, the deficiencies will be noted, and the form, as well as the manuscript when necessary, will be returned to the author for completion.*

Previous publication. If a report by the same author(s) or some of the same authors has been previously published in any medium that deals in any respect whatsoever with the same patients, same animals, same laboratory experiments, or same data, in part or in full, as those reported in the manuscript being submitted, two reprints of the article(s) or two copies of the manuscript, be it a full-length report or an abstract, must be submitted with the manuscript. Two copies of a new manuscript being prepared for possible publication also must be submitted. The author(s) should inform the Editor of the circumstances, similarities, and differences of the reports. This requirement also applies to the submission of a manuscript in which a few different patients, animals, laboratory experiments, or data were added to those reported in a previous publication or in a submitted or accepted manuscript. Articles previously published in another language will not be considered.

Human and nonhuman experimentation. It is assumed by the Editors that manuscripts emanating from a particular institution are submitted with the approval of the

requisite authority. Human experimentation that requires local institutional approval must have this approval *before the experiment is started* and approval must be so indicated in the *Material and Methods* section of the submitted manuscript. Reports of experiments on nonhuman animals or other species must *state in the* Material and Methods *section of the manuscript* that the guidelines for the care and use of the animals *approved by the local institution* were followed. The type of nonhuman animals or other species used in an investigation must be named in the title, abstract, key words, and *Material and Methods* section of the manuscript.

Authorship. For manuscripts with two or more authors, each author must qualify by having participated actively and sufficiently in the study that is being performed and reported. The inclusion of each author in the authorship list of a report is based only (1) on substantial contributions to (a) concept and design, or analysis and interpretation of data and (b) drafting the manuscript or revising it critically for important intellectual content; and (2) on final approval by each author of the version of the manuscript. Conditions 1 (a and b) and 2 must both be met. Others contributing to the work should be recognized separately in an Acknowledgment. *In the covering letter that accompanies the submitted manuscript, it must be confirmed that all authors fulfilled both conditions.*

Conflict of interest. Authors are expected to inform the Editor, in a letter accompanying the submitted manuscript, of any commercial association that might pose a conflict of interest, such as ownership, stock holdings, equity interests and consultant activities, or patent-licensing situations. Such information is confidential, is not given to the consultants, and does not play a part in the decision of the quality or timeliness of the manuscript. If the manuscript is accepted, the author and the Editor will determine how best to release the information. The usual and customary listing of sources of support and institutional affiliations on the title page is proper and does not imply a conflict of interest; only where there is a possible conflict of interest is the author(s) expected to inform the Editor.

Disclaimer. Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or Publisher, and the Editor(s) and Publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the Publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality photocopies of the manuscript and three sets of black-and-white glossy prints of illustrations are required. See "Color figures" and "Computer-generated figures" for special requirements. Manuscripts must be submitted in English.

Manuscripts must be typed double-spaced on one side only of 22 × 28 cm (8½ × 11 inch) white bond paper with 1-inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, condensation, abstract, body of text, acknowledgments, references, figure legends, and tables.

Title page. The title page (page 1) should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of each author and each author's highest academic degree (both MD and PhD are acceptable, but honors degrees are not permitted); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; source(s) of financial support; presented line, if applicable; disclaimers, if any; name, address, business and home telephone numbers, and fax number of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name, address, business and home telephone numbers, and fax number of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. *At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).*

Condensation. On page 2 of the manuscript provide a brief, concise condensation, typed double-spaced, that will appear with the title in publication of the Contents pages of the JOURNAL. It should be a single sentence, limited to a maximum of 25 words, delineating the essential point(s) made in the manuscript.

Abstract page including key words/phrases. On manuscript page 3, type the abstract, double-spaced, with the required margins and headed by the title of the article and name(s) of author(s). Below the abstract, list 3 to 5 *key words or short phrases* for indexing purposes.

A structured abstract is required for certain types of articles and a *standard abstract format* is required for other types of articles; therefore the author(s) should select and prepare the appropriate abstract to be used in the submitted manuscript. This applies to both independently submitted and society manuscripts.

Structured abstract. A structured abstract, limited to 150 words, is to be used for regular articles and society articles; excluded are Clinical Opinion, Current Development, case report, and brief communication articles. The structured abstract is to contain the following major headings: *Objective(s); Study Design; Results;* and *Conclusion(s).* The *Objective(s)* reflects the purpose of the study, that is, the hypothesis that is being tested. The *Study Design* should include the setting for the study, the subjects (number and type), the treatment or intervention, and the type of statistical analysis. The *Results* include the outcome of the study and statistical significance if appropriate. The *Conclusion(s)* states the significance of the results.

Standard abstract. The standard abstract format is required for Clinical Opinion, Current Development, case report, and brief communication articles. The standard abstracts for Clinical Opinion and Current Development articles are to be 50 to 150 words and standard abstracts for case reports and brief communications are limited to 50 words. Even though the formal names of these four types of articles are not used, an author should determine his/her type of manuscript and prepare the appropriate standard abstract, regardless of whether it is to be submitted independently or as a part of a society's transactions.

Text. Do not hesitate to write your manuscript in the first person and active voice if they are more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations, since the emphasis is on the "action" rather than on the person performing the action.

Only standard abbreviations are to be used. Consult the

Estimating length of manuscripts

With the exception of Current Development articles, the length of text material (introduction through *Comment* section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A text of 4200 words or more can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7-page article in the JOURNAL. The 2000 words of text alone makes approximately 8 pages of manuscript typed double-spaced with the required 1-inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 words in manuscript. Thus, if a greater number of illustrations and tables is used, the length of the text should be adjusted accordingly.

Council of Biology Editors Style Manual or the AMA's *Manual of Style.* Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify *Material and Methods*, *Results*, and *Comment*. Authors may wish to summarize their findings in a short paragraph at the end of the *Comment* section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the *Material and Methods* section describe briefly (but in sufficient detail to permit other workers to repeat the study) the plan, the patients, experimental animals or other species, material, and controls, the methods and procedures utilized, and the statistical method(s) employed.

In the *Results* section present the detailed findings. Include mentions of all tables and/or figures. Figures and tables should supplement, not duplicate, the text; presentation of data in either one or the other will suffice. Emphasize only your important observations; do not compare your observations with those of others. Such comparisons and comments are reserved for the *Comment* section.

In the *Comment* section state the importance and significance of your findings but do not repeat the details given in the *Results* section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgments. Acknowledge only persons who have made substantive contributions to the study.

References. A reasonable number (25) is allowed, except in case reports and brief communications (limited to 2) and in manuscripts for the Current Development section (for which there is no limit). Number references consecutively in the order in which they are mentioned in the text. Use the format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" (Vancouver style) (N Engl J Med 1991;324:424-8). Journal titles should conform to abbreviations used in *Cumulated Index Medicus.*

Examples (if six or fewer authors, list all; if seven or more authors, list three then et al.):

JOURNAL: Flamm BL, Dunnett C, Fischermann E, Quilligan EJ. Vaginal delivery following cesarean section: use of oxytocin augmentation and epidural anesthesia with internal tocodynamic and internal fetal monitoring. AM J OBSTET GYNECOL 1984;148:759-63.

BOOKS: Ledger WJ. Dystocia and prolonged labor. In: Wilson JR, Carrington ER, eds. Obstetrics and gynecology. St. Louis: CV Mosby, 1987 vol 8:474-93.

Personal communications and unpublished data, if essential, may be used but not as numbered references. If they are used, they are to be referred to, within parentheses, at the appropriate location in the text. If used, the author(s) must obtain written and signed permission for their use from the individual being quoted. *This signed permission must accompany the manuscript when it is submitted to the Editor.* Published abstracts can be used as numbered references; however, reference to the complete published article is preferred.

Figures. The term *figure* includes all types of illustrations such as graphs, diagrams, photographs, flow charts, and line drawings. A reasonable number of figures will be reproduced without charge, but special arrangements must be made with the Editors for color figures at an additional charge to the author. The quoted charge is per page of color, and as many as eight color figures can be included on one page if the color balance is appropriate.

Figures must be cited consecutively in the text in Arabic numerals and identified with a gummed label on the back of the figure with author(s) name(s), title of article, figure number, and top marked clearly. Consistency in size within the article is strongly preferred. Any special instructions regarding sizing should be clearly noted. Do not use paper clips or mar the surface of figures in any way. Figures will be returned only on request by the author.

For *black-and-white figures,* submit three sets of 3 × 4 inch (minimum) to 5 × 7 inch (maximum) unmounted, glossy prints. All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. All lettering must be in proportion to the drawing, graph, or photograph. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy prints with good black-and-white contrast.

For *color figures* submit original transparencies and two sets of unmounted prints on glossy (smooth surface) paper. Polaroid prints are not acceptable. Color transparencies must have a color balance (consistency in lighting and film speed) that is acceptable to the author and Editors before acceptance for publication. Please note that 35 mm transparencies are enlarged to twice their original size. If it is important to deviate from this standard, please so indicate when the material is submitted. The top, first author's last name, and figure number must be indicated on the front of each transparency and the back of each print.

Computer-generated figures must be legible and clearly printed in jet black ink on heavy coated paper with either a glossy or dull finish. Any patterns or shadings must be dark enough for reproduction and must be distinguishable from each other. Lines, symbols, and letters should be both smooth and complete. The legend should not appear on the figure. On the back of each figure the name of the first author and the figure number should be given and the top indicated. Three original individual laser or plotter prints are to be submitted *unmounted* with the manuscript. Laser prints should be full size at 300 dots per inch (DPI) or greater full-page resolution; multiple illustrations on a page cannot be accepted. Dot matrix prints and photographic halftones are not acceptable. *Color figures* are acceptable, but special arrangements must be made with the Editors. The colors used must be dark enough and of sufficient contrast for reproduction. With the exception of fluorescent colors, all colors can be reproduced in four-color figures.The preparation and submitting of color prints should follow the preceding guidelines for black-and-white computer-generated illustrations.

Legends to figures. Legends for all figures must be typed together in numeric order double-spaced on one sheet of paper (or more if necessary) separate from the text of the manuscript. This page must be numbered in sequence after the references. Titles should be included in the legend, not on the print. Original magnifications should be provided. If a figure has been taken from copyrighted material, the legend must give full credit to the original source.

Tables. Tables should be typed on separate sheets of paper, one table to a page, and included at the end of the text. They should be numbered in Roman numerals. Each table must be cited in sequence at an appropriate point in the text. Titles should be brief yet indicate clearly the purpose or content of each table, and each column should be precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. If a table or any part thereof has been taken from copyrighted material, a footnote to the table must give full credit to the original source. Arrangements must be made with the Editors for elaborate tables because of space limitations.

Permissions. Direct quotations, tables, or figures that have appeared in copyrighted material must be accompanied by written permission for their use from *the copyright owner and original author* along with complete reference information. Photographs of identifiable persons must be accompanied by signed releases. If not, all recognizable features must be masked.

Requirements for certain types of manuscripts

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include *standard abstract format*, of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title. If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

Clinical Opinion. Limit of 3000 words. Include *standard abstract format* of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Current Development. Limit of 6000 words. Include *standard abstract format* of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Letters to the Editors. *Letters to the Editors* must be submitted in duplicate, typed double-spaced, and the text of the manuscript must be limited to a maximum of 400 words (excluding references, name[s] and address[es] of the signer[s], and the phrase "To the Editors"). The submitted *Letter to the Editors* must be accompanied by a signed copyright statement. If there are two or more signers of the *Letter to the Editors,* one of the authors may sign the copyright statement but must add to the statement the following: "I sign for and accept responsibility for releasing this letter on behalf of any and all cosigners." These requirements apply to all types of *Letters to the Editors.* Letters should be sent to Dr. Zuspan.

Two types of letters will be considered for publication. (1) A *Letter to the Editors* commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. If the original author does not respond, a notation indicating "Response declined" will be published. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a *Letter to the Editors* will be considered for publication.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of $60 U.S., and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to Kay G. Goehler, Senior Manuscript Editor, Journal Editing, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Zuspan. No books will be returned.

Reprints

The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the Publisher with the author's consent.

Business communications

Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, or call Journal Advertising Production Manager (1-800-325-4177, ext. 4306, or 314-453-4306).

CHECKLIST AND COPYRIGHT STATEMENT

Both the checklist and the copyright statement forms **must be completed** and sent with each submitted manuscript. If **not** completed, these forms will be returned to the author for completion.

These items appear in each monthly issue of the JOURNAL. A photocopy may be used. An exposition of the requirements given in the checklist is in the Information for Authors, which is published in each issue of the JOURNAL.

CHECKLIST

General

—The original and two copies of the manuscript are submitted.
—The completed checklist is enclosed. The assignment of copyright signed by **all** authors accompanies the manuscript.
—Human experimentation has been approved by the local institution as stated in the *Material and Methods* section.
—Guidelines for the care and use of *nonhuman* animals or *other species* approved by the institution have been followed as indicated in the *Material and Methods* section. *The species is named in the title, abstract, key words, and* Material and Methods *section.*
—The covering letter with essential information is with the manuscript.
—All elements of the manuscript are typed in English double-spaced on bond paper with 1-inch margins at top, bottom, and sides.
—All pages are numbered in the following order: title page, condensation, structured or standard abstract, body of the text, acknowledgments only of persons who have made substantive contributions to the study, references, legends, and tables.
—Signed, written permission from both the copyright holder and the original author for the use of tables, figures, or quotations previously published and their complete references are enclosed with the manuscript.
—Signed, written permission for the use of quotations of personal communications and unpublished data has been obtained from the person(s) being quoted and is enclosed.

Authorship

—In the covering letter that accompanies the submitted manuscript I/we have confirmed that all authors fulfilled both conditions required for authorship.

Conflict of interest

—In the covering letter that accompanies the submitted manuscript the commercial association of the author or of any coauthors that might pose a conflict of interest is described.

Previous publications

—Enclosed with the submitted manuscript are two reprints each of articles the author and/or some of the coauthors have previously published, have submitted for possible publication, or have in manuscript form dealing with same patients, same animals, same laboratory experiment, or same data, in part or in full, as those reported in the submitted manuscript. Further explanation is provided in the covering letter that accompanies the submitted manuscript.
—Similarities, differences and explanation are provided in the covering letter that accompanies the submitted manuscript.

Reviewers

—Names and addresses of three suggested reviewers are enclosed.

Title page

—These elements are given in the following sequence, and are typed double-spaced.
—Title.
—Author(s) name(s) and highest academic degree(s) are shown.
—City(ies), state(s), and country other than United States in which the study was conducted are given.
—The name(s) of the institution(s) section(s), division(s), department(s) in which the study was performed is provided and the institutional affiliation(s) of the author(s) at the time of the study is indicated.
—Acknowledgment of financial support is cited.
—Name, address, business and home telephone numbers, and fax number of author to whom requests for reprints are to be sent are included.
—If reprints will not be available, this has been stated on the title page.
—If the corresponding author is different from the author to whom reprint requests are to be sent, his/her name, address, business and home telephone numbers, and fax number have been added.
—At the bottom of the page, a running head not exceeding 52 characters (including word spaces) has been typed.

Condensation

—On a separate sheet of paper, page 2 of the manuscript, a single sentence limited to 25 words delineating the essential point(s) is typed double-spaced.

Abstract and key words or short phrases

—The abstract (structured or standard format) is typed double-spaced with required margins on page 3 headed by the title and author(s) name(s). Beneath the abstract 3 to 5 key words or short phrases are typed.
—A *structured abstract,* with 150 words or less, is submitted as required for regular articles and society regular-type articles. The abstract contains the four required major headings: Objective(s), Study Design, Results, and Conclusion(s), each with a brief adequate presentation.
—A *standard abstract* is submitted as required for Clinical Opinion and Current Development articles with 50 to 150 words and for case reports and brief communications articles with a maximum of 50 words, be they independent or society articles.

References

—Are typed double-spaced.

—Are numbered consecutively in the order they are cited in the text.

—The format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" is used. Examples shown in Information for Authors have been followed.

—Personal communications and unpublished observations are not used as numbered references but are mentioned in the text with the written approval of the person being quoted. The signed approval is enclosed.

Figures

—Each is numbered with an Arabic numeral and cited in numeric sequence in the text.

—Three sets of unmounted glossy prints for *black-and-white* figures are submitted, properly numbered, labeled, and *top indicated* on the back of each print.

—Three sets of original computer-generated figures printed on heavy coated paper with either a glossy or dull finish, unmounted, each one on a page, and properly labeled on the back and *top indicated* are submitted. None are dot matrix or photographic prints.

—Original transparencies of *color photographs* appropriately numbered and identified and *top indicated* are submitted along with two sets of unmounted prints on glossy paper, numbered and identified on the back.

Figure legends

—Are provided for each figure.

—Are numbered and typed together in numeric order on one sheet of paper (more if necessary). The page is numbered in sequence after the References page(s).

Tables

—Each table headed by a title and numbered in Roman numerals is typed double-spaced on a separate page.

—Tables are cited in numeric sequence in the text.

Continuous combined conjugated equine estrogen–progestogen therapy: Effects of medroxyprogesterone acetate and norethindrone acetate on bleeding patterns and endometrial histologic diagnosis

T.C. Hillard, MD, N.C. Siddle, MD, M.I. Whitehead, MD, D.I. Fraser, MD, and J. Pryse-Davies, MD

London, England

OBJECTIVES: This study was designed to assess the incidence of amenorrhea with continuous combined therapy by using two different progestogens and to determine whether early bleeding predicts subsequent bleeding and endometrial response.

STUDY DESIGN: Seventy-nine postmenopausal women on sequential estrogen-progestogen treatment were switched to continuous combined estrogen-progestogen therapy comprising conjugated equine estrogens 0.625 mg daily with either norethindrone acetate 0.35 mg twice daily or medroxyprogesterone acetate 2.5 mg twice daily added continuously for 78 weeks. All bleeding was recorded, and endometrial biopsies were performed at 26 and 78 weeks.

RESULTS: Only one third of the women who starting the study had amenorrhea by week 78, but 46 (62%) of these women had withdrawn, mainly because of chronic irregular bleeding. Endometrial atrophy was observed in the majority of biopsy specimens. The two progestogens had similar effects. Bleeding patterns were useful predictors of subsequent bleeding, but not of endometrial response.

CONCLUSIONS: Persistent irregular bleeding is common with continuous combined estrogen-progestogen therapy. Women with persistent early bleeding should probably revert to sequential treatment. Regular endometrial sampling is advised. (AM J OBSTET GYNECOL 1992;167:1-7.)

Key words: Continuous combined estrogen-progestogen, endometrial bleeding

Progestogen addition to estrogen replacement therapy although desirable for endometrial protection,[1, 2] has certain disadvantages. Progestogens may cause physical and psychologic side effects,[3] partially reverse some of the beneficial lipid and lipoprotein effects seen with estrogen-only therapy,[4, 5] and with sequential addition cause regular uterine bleeding in approximately 85% of women without hysterectomies.[6, 7] Although the bleeding pattern can predict the endometrial response and thereby reduce the need for endometrial biopsy,[8] the recurrence of withdrawal bleeding is unacceptable to some women.

Continuous combined estrogen-progestogen therapy has been proposed to overcome or reduce these problems. Progestogens have antimitotic actions on the endometrium[9, 10]; if given continuously, progestogens should induce endometrial atrophy, which, in turn, will produce amenorrhea. Furthermore, with continuous administration lower daily doses should be effective; thus the unwanted physical, psychologic, and metabolic effects of progestogens may be reduced.

The published experience of continuous combined estrogen-progestogen therapy is, however, limited.[11] Long-term safety data are sparse, and only one report[12] has provided endometrial data on patients taking continuous combined estrogen-progestogen therapy for

more than 12 months; 21 patients were studied at 18 months.

We have compared the effects of two commonly prescribed progestogens, norethindrone acetate and medroxyprogesterone acetate, when given as continuous combined therapy, on bleeding patterns and endometrial histologic diagnosis over an 18-month period. To clarify the effect of duration of therapy on the development of amenorrhea we separated our bleeding data into two time periods; weeks 1 through 25 and 26 through 78.

Material and methods

Seventy-nine postmenopausal women with intact uteri attending the Menopause Clinics at King's College Hospital and the Chelsea Hospital for Women were recruited and gave informed consent. All were taking oral estrogen replacement therapy continuously (every day), with a progestogen added for the first 10 to 12 days of each calendar month. All but one were taking conjugated equine estrogens 0.625 mg daily; the exception took piperazine estrone sulfate, and she was changed to conjugated equine estrogens at the beginning of continuous combined treatment. Forty-five patients were taking norethindrone acetate as their sequential progestogen, 19 medroxyprogesterone acetate, 11 norgestrel, 3 dydrogesterone, and 1 oral progesterone.

At enrollment all patients were either postmenopausal (at least 12 months since their last menstrual period) or had been receiving sequential therapy for relief of menopausal symptoms for ≥3 months. The majority had undergone endometrial biopsies during the previous 2 years. Two biopsy specimens showed mild cystic hyperplasia, and one showed secretory activity with an area of cystic change. All others showed normal histologic changes consistent with phase of treatment.

After enrollment patients continued with sequential estrogen-progestogen therapy for two more cycles for collection of baseline physical and psychologic data. All patients had regular withdrawal bleeding during these cycles. Six days after stopping the sequential progestogen patients started continuous combined estrogen-progestogen therapy and were allocated to either continuous norethindrone acetate 0.35 mg twice daily (morning and evening) or medroxyprogesterone acetate 2.5 mg twice daily in addition to the daily conjugated equine estrogens 0.625 mg. Continuous combined estrogen-progestogen therapy was administered for 78 weeks and patients were reviewed after approximately 12, 25, 52, and 78 weeks of continuous combined estrogen-progestogen therapy.

The intensity of all bleeding was recorded every day on a bleeding chart relative to the normal menstrual loss with a four-point scale; spotting, mild, moderate, or heavy. Patients also recorded when tablets were taken and noted any event that might provoke bleeding, such as concurrent antibiotic use.

Biopsy specimens were obtained either by dilation and curettage when the patient was under general anesthesia or by suction curettage (Vabra, Berkeley Medevices, Berkeley, Calif.) performed as an outpatient procedure. All tissue was placed immediately into formol–acetic acid for histologic examination. The features assessed were those of the normal menstrual cycle. Biopsies were performed after 25 and 78 weeks of continuous combined estrogen-progestogen therapy.

All treatment-related side effects were recorded. Various options to adjust treatment were incorporated into the protocol. If menopausal symptoms recurred after the patient changed to continuous combined estrogen-progestogen therapy, the clinician could increase the dose of conjugated equine estrogens. With chronic, irregular bleeding patients were given three options: (1) withdraw, (2) continue with current treatment, or (3) increase the dose of either the estrogen or the progestogen. The success of the latter was assessed by reviewing the bleeding records for the subsequent 6 weeks. If the bleeding was reduced or if amenorrhea developed, the change was regarded as successful; if the bleeding did not abate, the change was regarded as unsuccessful.

Statistical methods. Comparison of the demographic data between the two groups was made with unpaired Student's t test.

Results

Data from five patients were excluded. Two failed to complete the bleeding charts satisfactorily, two missed tablets on so many occasions that the bleeding pattern could not be interpreted, and one took the incorrect dose of medication. Thus analyzable data were available from 74 patients, 46 on norethindrone acetate and 28 on medroxyprogesterone acetate. There were no significant differences between the norethindrone acetate and medroxyprogesterone acetate groups for mean age (55.1 and 54.9 years, respectively), mean time since menopause (73.8 and 71.2 months), and mean weight (60.9 and 63.4 kg, respectively).

Reasons for discontinuation. Seventeen (23%) of the 74 patients withdrew during the first 25 weeks, and 29 (39%) withdrew between weeks 26 and 78. Thus 28 (38%) patients completed the study. The reasons are shown in Table I. The most common reason with both progestogens over the entire study was chronic bleeding. It is noteworthy that some of the patients who withdrew because of chronic bleeding were not necessarily those who experienced the longest bleeding.

Table I. Patients who withdrew from study according to type of progestogen and time period

Reason for withdrawal from study	Weeks 1-25				Weeks 26-78			
	Norethindrone acetate		Medroxyprogesterone acetate		Norethindrone acetate		Medroxyprogesterone acetate	
	No.	%	No.	%	No.	%	No.	%
Chronic bleeding	7	15*	4	14*	5	11	3	11*
Side effects of progestogen	3	7	0	0	4	9	2	7
Miscellaneous	0	0	2	7	8	17	4	14
Lost to follow-up	1	2	0	0	2	4	1	4
TOTAL	11	24	6	21	19	41	10	36

*Includes five patients (three receiving norethindrone acetate and two receiving medroxyprogesterone acetate) who also reported physical and psychologic progestogen-induced side effects.

Breast tenderness, fluid retention, and mood changes were the most common side effects of progestogen.

Over the entire study 14 patients withdrew for miscellaneous reasons; these included mildly elevated blood pressure, fibroids requiring hysterectomy, recurrence of menopausal symptoms not controlled by increasing the dose of conjugated equine estrogens, and breast cancer. The remainder of the miscellaneous withdrawals were not caused by side effects. Six patients violated the protocol, and four patients wanted to stop therapy for personal reasons such as anxieties about cancer. An additional four patients were lost to follow-up.

Treatment adjustments. Twenty-three patients underwent a total of 26 treatment adjustments. Five patients increased the dose of conjugated equine estrogens for symptom recurrence: this was successful in four. Twenty-one adjustments were made for bleeding: 13 were increases in the dose of conjugated equine estrogens, 4 increases in the dose of norethindrone acetate (3 to 0.7 mg twice daily, 1 to 1.5 mg twice daily) and 4 increases in the dose of medroxyprogesterone acetate to 5 mg twice daily. Seven, three, and one of these adjustments, respectively, were successful.

Eight of the patients who completed the study underwent at least one treatment adjustment; 20 of the patients who completed the study took the same medication throughout the study.

Percentage of patients with amenorrhea. To assist with the expression and comprehension of these data, the study has been divided into 6-week intervals. Any bleeding considered attributable to missed tablets or concomitant antibiotic administration or that occurred within 14 days of an endometrial biopsy was excluded.

The percentage of patients in the two progestogen groups reporting amenorrhea at each 6-week interval throughout the study is shown in Fig. 1 and is expressed as a percentage of patients remaining in the study and as a percentage of patients who started the study.

Bleeding episodes. For the two phases of the study (weeks 1 through 25 and 26 through 78) the total days of bleeding was calculated for each patient. Each day on which any bleeding was reported was defined as one bleeding episode.

A total of 1944 days of bleeding was recorded during weeks 1 through 25 and 1091 days during weeks 26 through 78. Bleeding was scored as moderate or heavy on 130 (6.6%) and 59 (5.4%) days, respectively. The largest amount of bleeding experienced by any patient was 161 days in weeks 1 through 25 and 127 days in weeks 26 through 78. The patterns in the two progestogen groups were similar. (Further data are available on request.)

Table II reports the relationship between the total duration of bleeding experienced during the first 25 weeks and that reported between weeks 26 through 78. The 17 patients who withdrew during the first 25 weeks are not included; one patient who withdrew at the beginning of week 26 has also been excluded.

Endometrial histologic diagnosis. Biopsies were performed on 51 of the 57 patients who completed the first 25 weeks and on 17 of the 28 patients who completed week 78. The results for the two progestogens are shown in Table III. No hyperplasia or carcinoma was observed in any sample (including those in which the tissue was too scant for reliable interpretation). In spite of thorough curettage, a sample inadequate for reliable interpretation or "no tissue" was obtained on 54 occasions.

Six patients completed week 25 but did not have a biopsy performed; three patients declined biopsies and withdrew from the study because of chronic bleeding. Two refused biopsy but wished to continue in the study; one of these subsequently underwent a biopsy procedure at week 78. Outpatient curettage was not possible in one patient at week 25 because of cervical stenosis; she declined dilation and curettage.

Mild cystic hyperplasia had been diagnosed in three patients at biopsy before continuous combined estrogen-progestogen therapy; at week 25 late secretory en-

		Duration of bleeding (days)			
Duration of bleeding (days)	*No. of patients*	*0*	*1-9*	*10-59*	*≥60*
Amenorrhea	10	10	0	0	0
1-9	17	13	2	2	0
10-59	21	3	8	7	3
≥60	8	0	2	2	4

Data for norethindrone acetate and medroxyprogesterone acetate groups are combined. Only includes patients who completed 26 weeks (17 withdrew in weeks 1 through 25; 1 withdrew in week 26).

dometrium was diagnosed in one of these patients and atrophic endometrium was diagnosed in another. The third patient withdrew at 12 weeks because of progestogen-induced side effects.

Eleven patients declined the second biopsy. Between weeks 26 and 78, 8 had had amenorrhea, 1 had spotted for 7 days, and 2 had experienced prolonged bleeding (68 and 118 days).

Relationships between endometrial histologic diagnosis and duration of bleeding. Because norethindrone acetate and medroxyprogesterone acetate produced similar histologic results for the two phases of treatment (Table III), the data for the two progestogens have been combined. In Table IV the histologic results are presented relative to the number of days of bleeding experienced during the first 25 weeks and between weeks 26 and 78. The second number is an identical expression of the histologic results but related to the total number of days of bleeding recorded during the 6-week interval immediately before the biopsy.

Comment

Only 28 patients completed the study; these numbers were too small for statistical comparisons between the norethindrone acetate and medroxyprogesterone acetate groups. Although four patients were lost to follow-up and 10 of the 14 miscellaneous withdrawals were not caused by side effects (Table I), 32 (43%) patients discontinued the study because of problems with treatment. This contrasts with our recent studies of sequential regimens, also of 18 months' duration,[13] in which only 15% of women receiving oral and 3% receiving transdermal sequential therapies discontinued treatment because of side effects.

The most common problem was chronic irregular bleeding (Table I). Although the majority of the bleed-

ing was spotting or light, it could be very prolonged. Four patients with bleeding for >60 days in either time period completed the study, but we doubt whether such perseverance will occur in a routine clinical environment.

Various strategies for reducing the incidence of bleeding have been proposed. Because norethindrone acetate and medroxyprogesterone acetate are rapidly cleared from plasma, we administered these progestogens twice daily to try to provide more constant plasma levels. Our results show that this is not more successful than once daily administration. Staland,[14] Mattson et al.[15] and Hargrove et al.[16] all reported increased incidence of bleeding among perimenopausal women. Only five of our women were within 12 months of their last menstrual period; the mean duration since menopause was approximately 6 years. However, like 93% of those in the study of Magos et al.,[12] all our patients had received sequential therapy before commencing continuous combined estrogen-progestogen therapy. Magos et al.[12] reported dropout rates of between 20% and 49%, depending on the estrogen dose; these rates are comparable with those reported here but are higher than those 0% to 33% rates reported with 9 to 12 months of continuous combined estrogen-progestogen therapy in women previously untreated for at least 4 weeks.[14-21]

Various explanations for the higher rates of discontinuation have been observed by Magos et al.[12] and us. Sequential therapy may have a carryover effect that increases the frequency and duration of irregular bleeding after the change to continuous combined estrogen-progestogen therapy. However, if this carryover effect is the mechanism, it is difficult to understand biologically why it should be so prolonged. Between weeks 26 and 78, chronic irregular bleeding occurred not infrequently and resulted in eight withdrawals (Table I). Alternatively, patients well established on sequential therapy who experience regular withdrawal bleeding may be less prepared than previously untreated women to have chronic, irregular bleeding. Additionally, continuous as compared with sequential administration of the progestogen can cause adverse symptomatic and psychologic changes (Table I), and four patients suffered recurrences of their original symptoms with continuous combined estrogen-proges-

togen therapy, probably because of progestogenic antagonism of estrogen benefits.

The last alternative is that various authors have expressed their results differently. Although there is agreement that the percentage of patients with amenorrhea increases over time (Fig. 1) we believe that because of the high proportion of dropouts resulting from chronic bleeding, data on the incidence of amenorrhea should be displayed not only relative to the numbers of patients remaining in the study but also relative to the numbers starting the study. In this study persistent amenorrhea was eventually achieved by only approximately one third of patients (Fig. 1) who started continuous combined estrogen-progestogen therapy.

None of our attempts to reduce bleeding were uniformly successful, and these results add to the already-confusing literature on the optimal strategy for patients with chronic bleeding. Some authors have reported better results with higher progestogen doses,[12, 17] but others have reported the converse.[20]

There was no evidence of endometrial disease in this study. The majority of biopsies at both time periods resulted in "no tissue," a sample too small for reliable assessment or endometrial atrophy (Table III). Endometrial histologic diagnosis could not be predicted reliably from the bleeding pattern, although complete amenorrhea was only associated with endometrial atrophy or with secretory endometrium (Table IV).

We regard proliferative endometrium with continuous combined estrogen-progestogen therapy as indicating a lack of progestational effect. Over a long term this might increase the risk of endometrial carcinoma. This individual variation in response to the added progestogen, with some patients exhibiting a good effect (i.e., atrophy) but others none, is well recognized with sequential therapies.[22] Proliferative endometrium was diagnosed twice at the week 25 biopsy. One patient had experienced only 1 day of spotting up to week 25 and thereafter had amenorrhea. The second patient discontinued treatment at week 61, having bled 282 days.

Our data suggest that whereas amenorrhea indicates progestational activity within the endometrium, durations of bleeding of 1 day can be associated with lack of endometrial response to the administered progestogen. We leave the reader to draw the conclusions about the need for biopsy in patients with minimal bleeding.

Women who have amenorrhea from the outset are likely to continue to have it, and the majority of those with bleeding for <10 days during the first 25 weeks of therapy will also have amenorrhea as the duration of treatment is extended. In those whose bleeding is of moderate duration (10 to 59 days) during the first 25 weeks, it is more difficult to predict future bleeding, which can be variable (Table II). Conversely, in those with chronic bleeding during the first 25 weeks it is likely to continue and amenorrhea is unlikely. These women may be best advised to switch to sequential therapy.

We thank Mrs. Angela Short for her help in preparing this manuscript.

Macrosomia in postdates pregnancies: The accuracy of routine ultrasonographic screening

Raphael N. Pollack, MDCM, Gittit Hauer-Pollack, MSc, and Michael Y. Divon, MD
Bronx, New York

OBJECTIVE: The purpose of this study was to assess the efficacy of routine ultrasonographic assessment of fetal weight in predicting fetal macrosomia in postdates pregnancies.
STUDY DESIGN: A total of 519 pregnancies of ≥41 weeks' duration were subjected to ultrasonographic estimation of fetal weight within 1 week of delivery. Estimated fetal weights were compared with birth weights. Linear regression analysis was performed and prediction limits for estimated fetal weights were generated.
RESULTS: Twenty-three percent of infants had birth weights ≥4000 gm and 4% had birth weights ≥4500 gm. The mean percent absolute error was 7.7%. At a birth weight of >3750 gm, the Hadlock model (which uses abdominal circumference and femur length) systematically overestimated the birth weight. The sensitivity, specificity, and positive and negative predictive values for the ultrasonographic diagnosis of macrosomia were 56%, 91%, 64%, and 87%, respectively. The prediction limits generated determine the range of birth weights predicted for a given estimated fetal weight.
CONCLUSION: Routine ultrasonographic screening for macrosomia in postdates pregnancies is associated with a relatively low positive predictive value. (AM J OBSTET GYNECOL 1992;167:7-11.)

Key words: Postdates pregnancies, fetal macrosomia, ultrasonographic prediction of fetal weight

Fetal macrosomia is a condition that may be associated with significant obstetric morbidity. The macrosomic fetus is at elevated risk for birth asphyxia and birth trauma; the mother carrying a fetus with macrosomia may be at increased risk of both operative delivery and postpartum hemorrhage.[1-4] Factors that predict fetal macrosomia include maternal weight gain of >20 kg, maternal obesity, diabetes, and antecedent pregnancies that have been delivered ≥7 days post term.[1, 2]

Postterm pregnancies have traditionally been considered to be at elevated risk of adverse outcome and have therefore been subjected to fetal surveillance. Approximately one fifth of all pregnancies continue beyond 41 weeks' gestation,[5] and postdate pregnancies represent a significant proportion of patients undergoing fetal surveillance.[6] These surveillance programs have focused on the detection of fetal hypoxia associated with uteroplacental insufficiency.[7] To this end fetal heart rate monitoring, biophysical profile, and assessment of amniotic fluid volume have been used. The presence of fetal macrosomia, however, with its attendant risk to

mother and fetus, has not been sought on a routine basis.

Chervenak et al.[8] have recently proposed that ultrasonographic estimation of fetal weight may be useful in identifying macrosomic fetuses and should be incorporated into the surveillance of the postterm fetus. The identification of the macrosomic fetus may provide the clinician with important information that may alter the delivery management. The purpose of our study was to prospectively evaluate the accuracy of ultrasonographic fetal weight estimation in a population at elevated risk for fetal macrosomia, namely patients with postterm pregnancies. We also proposed to develop prediction limits to assist in the clinical interpretation of ultrasonographic fetal weight estimations.

Material and methods

Between January 1989 and September 1990 all patients seen for fetal surveillance because of prolonged pregnancy at the Weiler Hospital of the Albert Einstein College of Medicine underwent ultrasonographic estimation of fetal weight, assessment of amniotic fluid volume, and nonstress testing. A total of 519 patients were delivered within 1 week of fetal weight estimation. These patients formed the study group. Only patients with singleton, uncomplicated pregnancies of >41 weeks' gestation were included in the study. Gestational age was based on the last menstrual period and early ultrasonographic examination when available. Gestational age was based on ultrasonographic examination only when there was a discrepancy of >10 days between menstrual dates and ultrasonographic dates during the first trimester of pregnancy. After the initial visit all patients were evaluated semiweekly.

Ultrasonographic examination was performed with a real-time scanner (Aloka 650, Corometrics, Wallingford, Conn.) with a 3.5 mHz linear array probe. Measurements of biparietal diameter, abdominal circumference, and femur length were performed with standard techniques.[9] The estimated fetal weight based on abdominal circumference and femur length was derived from the tables of Hadlock et al.[10] Actual birth weights were then compared with estimated fetal weight. Percentage differences between estimated fetal weight and actual birth weight were calculated for each patient. The sensitivity, specificity, and positive and negative predictive values of an estimated fetal weight of ≥4000 gm to predict a birth weight of ≥4000 gm were determined. Regression analysis of birth weight on estimated fetal weight and calculation of 70th, 80th, 90th, and 95th percentile prediction limits were calculated with statistical software (GBSTAT 2.0, Dynamic Microsystems, Silver Spring, Md.) (see Appendix).

Results

Five hundred nineteen patients referred for antenatal surveillance because of postdates pregnancy were delivered within 1 week of ultrasonographic estimation of fetal weight. The mean estimated fetal weight was 3640 ± 461 gm (mean ± SD). One hundred three (19.9%) fetuses were estimated to weigh ≥4000 gm; 24 (4.6%) were estimated to weigh ≥4500 gm. The mean

Table I. Prediction limits for ultrasonographic estimates of fetal weight

Estimated fetal weight (gm)	*Predicted birth weight (gm)*	*Percentile*			
		70th	*80th*	*90th*	*95th*
3500	3578	3174-3982	3081-4075	2939-4217	2817-4340
3750	3741	3337-4145	3244-4238	3102-4380	2980-4502
4000	3903	3499-4308	3406-4402	3265-4543	3142-4665
4250	4066	3661-4471	3568-4564	3426-4706	3303-4829
4500	4229	3823-4634	3730-4728	3588-4870	3465-4993
4750	4391	3985-4798	3891-4891	3748-5034	3626-5157
5000	4554	4147-4961	4053-5055	3910-5198	3786-5322

birth weight of these infants was 3670 ± 446 gm (mean ± SD). One hundred nineteen (22.9%) infants weighed ≥4000 gm and 21 (4.1%) weighed ≥4500 gm.

The mean absolute error of the ultrasonographic estimated fetal weight, defined as the absolute value of birth weight − estimated fetal weight, was 279 gm, and the mean percent absolute error, defined as |birth weight − estimated fetal weight/birth weight| × 100, was 7.6% ± 6.8% (mean ± SD). Of weight estimates, 41.6% were within 5% of the actual birth weight, 72.5% were within 10%, and 89.4% were within 15%. The sensitivity, specificity, and positive and negative predictive values of an estimated fetal weight ≥4000 gm in predicting macrosomia (i.e., birth weight ≥4000 gm) were 56%, 91%, 64%, and 87%, respectively. When the estimated fetal weight used to predict macrosomia was increased to ≥4500 gm, the sensitivity, specificity, and positive and negative predictive values were 15%, 99%, 81%, and 80%, respectively.

These data describe the accuracy of ultrasonographic estimation of fetal weight when applied to our study population. To assess the accuracy of the ultrasonographic prediction of macrosomia when applied to an individual patient, prediction limits were generated. A regression of birth weight and estimated fetal weight with the associated 80th, 90th, and 95th percentile prediction limits is shown in Fig. 1. This regression is described by the following equation: $Y = 1302.062 + (0.6504)X$, where Y = birth weight and X = estimated fetal weight. The correlation coefficient of this equation is 0.6731, and the relationship is significant ($p = 0.0001$).

With this regression line the birth weight associated with a given estimated fetal weight can be predicted. The predicted birth weight and the 70th, 80th, 90th, and 95th percentile prediction limits associated with a given estimated fetal weight are shown in Table I. In infants whose birth weight exceeded approximately 3750 gm the Hadlock model, which uses abdominal circumference and femur length to estimate fetal weight, systematically overestimated the actual birth weight. The prediction limits show that for a given estimated fetal weight a range of predicted birth weights may be derived. The width of this range is dependent upon the level of confidence placed in the prediction. Thus the range of the 95th percentile prediction limit is substantially greater than that of the 70th percentile prediction limit. Table I indicates that the predicted birth weight associated with an estimated fetal weight of 4500 gm was 4229 gm. This estimated fetal weight was associated with a predicted birth weight ranging from 3823 to 4634 gm 70% of the time. Similarly, 95% of the time the same estimated fetal weight was associated with a predicted birth weight ranging from 3465 to 4993 gm.

Comment

Although the increased morbidity and mortality associated with postdate pregnancy has long been appreciated, only recently has the contribution of macrosomia to these adverse outcomes been understood.[8] Boyd et al.[1] noted that the incidence of fetal macrosomia increases with increasing gestational age. These results have been confirmed by Arias,[2] who suggested that ultrasonographic assessment of fetal weight be incorporated into the surveillance of postdates pregnancies. Chervenak et al.[8] have shown that the presence of fetal macrosomia increases with increasing gestational age and that this may be associated with a significant increase in cesarean sections performed for labor disorders. Those authors have focused attention on the fact that postponing delivery in postdates pregnancies may ultimately increase the incidence of fetal macrosomia, thereby increasing the rate of operative delivery.

The implementation of a screening program for fetal macrosomia is predicated on two assumptions. First, it must be assumed that the techniques used in screening can accurately predict fetal macrosomia. Second, implementation of a screening program presupposes that the accurate prediction of macrosomia mandates a well-defined plan of management. Our study examines the validity of the first assumption. Although clinical esti-

mation of fetal weight and measurement of symphyseal-fundal height have long been used to diagnose fetal macrosomia, the accuracy of these techniques is limited.[10-19] Ultrasonographic estimation of fetal weight with the formula of Hadlock et al.[10] has been shown to be the most effective formula when used in late pregnancy.[17] This formula is also particularly well suited for use in the postdates pregnancy because it makes use of abdominal circumference and femur length. We have previously shown that because of the position of the fetal head, the biparietal diameter may not be measurable in as many as one fifth of postdates patients subjected to ultrasonographic examination.[8] Although the formula of Hadlock et al.[10] may be superior to other formulas, our data show it too can be associated with a significant overestimation. The mean percent absolute error observed with this formula was 7.7%. We have observed that only 56% of fetuses with macrosomia were identified as such on the basis of the ultrasonographic weight estimation. When a fetus was diagnosed as having macrosomia on the basis of an ultrasonogram, the birth weight was found to be >4000 gm in only 64% of cases.

The inherent inaccuracies of the ultrasonographic techniques used to diagnose fetal macrosomia have placed the clinician in a most unenviable position. In the presence of an ultrasonographic diagnosis of macrosomia the clinician may opt for a trial of labor with its attendant risk of labor abnormalities and birth trauma. Alternately, an abdominal delivery with its attendant morbidity can be chosen as long as it is appreciated a priori that in 36% of cases the antenatal diagnosis of macrosomia will not be substantiated.

An informed clinical interpretation of an estimated fetal weight must integrate a variety of parameters, including the sensitivity, specificity, and positive and negative predictive value of the test in predicting fetal macrosomia. This interpretation must also reflect that as the estimated fetal weight increases, so does the likelihood that a birth weight of >4000 gm will be observed. The range of birth weights predicted for a given estimated fetal weight is an additional parameter of clinical relevance. This range is referred to as the prediction limit. For a given estimated fetal weight a 90th percentile prediction limit provides the range of birth weights observed 90% of the time. The prediction limits shown in Table I represent a clinically useful method of relating ultrasonographic estimated fetal weights to expected birth weights. This table indicates that to be 70% confident that a predicted birth weight will be >4000 gm, an estimated fetal weight of approximately 4750 gm is required. Of the five hundred nineteen patients studied, only 1% had an estimated fetal weight of >4750 gm.

In conclusion, we have demonstrated that prospective ultrasonographic screening in a patient population at elevated risk of macrosomia is associated with a rather low positive predictive value. Therefore implementation of such screening is of limited use. Further improvements in the techniques used to predict fetal macrosomia must occur before the introduction of such screening programs.

Appendix

Calculation of prediction limits. The $(1 - \alpha)$ percent prediction interval for an individual predicted birth weight based on an estimated fetal weight is defined by:

$$\hat{Y}_{n+1} \pm t_{n-2,\alpha/2} \sqrt{\left[1 + \frac{1}{n} + \frac{(X_{n+1} - \overline{X})^2}{\sum_{i=1}^{n} (X_i - \overline{X})^2}\right] S_e^2}$$

where $\hat{Y}_{n+1}$ is the predicted birth weight and X_{n+1} is the corresponding estimated fetal weight.

S_e, an estimate of the SD of the birth weights about the regression line, is equal to:

$$\sqrt{\frac{\Sigma(Y_i - \hat{Y}_i)^2}{n - 2}}$$

The X_i and $\overline{X}$ represent the estimated fetal weights and average estimated fetal weights, respectively, for our sample size n. $t_{n-2,\alpha/2}$ is the Student t distribution value with $(n - 2)$ degrees of freedom.[20]

The clinical diagnosis of asphyxia responsible for brain damage in the human fetus

James A. Low, MD, Lynn L. Simpson, MD, and David A. Ramsey, MB, ChB
Kingston, Ontario, Canada

OBJECTIVE: Our objective was to review the clinical findings in infants who died in the perinatal period with brain damage attributable to asphyxia.
STUDY DESIGN: The neuropathologic findings in 208 perinatal deaths have been reviewed. Thirty cases (22 fetal, eight newborn) had evidence of white matter or neuronal necrosis due to asphyxia. The clinical course of the pregnancy in 22 cases with brain damage attributable to fetal asphyxia were examined.
RESULTS: The diagnosis of asphyxia was confounded by several factors: (1) asphyxia may occur at any time in the last half of pregnancy, (2) 50% of the antepartum asphyxia occurred when the pregnancy had no risk factors, (3) periodic fetal assessment in the complicated preterm pregnancies failed to identify the asphyxial episodes in the remaining cases of antepartum asphyxia, and (4) indicators of fetal asphyxia in the cases of intrapartum fetal asphyxia were obtained after the central nervous system injury had occurred.
CONCLUSION: These findings highlight the difficulty in the diagnosis of fetal asphyxia at a stage that could permit intervention to prevent brain damage. (Am J Obstet Gynecol 1992;167:11-5.)

Key words: Fetal asphyxia, brain damage, clinical diagnosis

Studies in the monkey and lamb have demonstrated that fetal asphyxia can cause central nervous system injury and corresponding motor and cognitive deficits in surviving animals.[1-4] However, there is no consensus as to how much of the burden of neurologic handicap in the community can be attributed to perinatal asphyxia in humans.[5] Much of this continuing dilemma is due to the absence of a specific diagnostic marker for fetal asphyxia; this absence hampers a reliable interpretation of the data derived from epidemiologic studies.

The introduction of risk scoring and the assessment of fetal behavior has improved the identification of the fetus at risk for asphyxia, although blood gas and acid-base assessment of fetal blood can provide a specific diagnosis in some cases. However, in spite of these developments, there is no evidence that these clinical and technologic improvements have led to a decrease in the incidence of cerebral palsy.[6, 7]

An accurate description of the neuropathology that is responsible for motor and cognitive deficits in children is an important step in our progress to the understanding and prevention of cerebral palsy and men-

tal retardation. Although the neuropathologic abnormalities associated with these disasters in children and young adults have been well described, it has been virtually impossible to confidently attribute the structural changes in the brain to events that may have occurred during the perinatal period, many years before the death of the patient. What has been missing are studies that attempt to correlate clinical abnormalities that are observed in the fetus and newborn infant with the neuropathologic abnormalities in those who die. Such a study would give some idea of the incidence of these severe insults and would allow markers of asphyxia to be identified.

To examine these questions we have reviewed the clinical findings in a series of infants who died in the perinatal period and in whom brain damage attributable to asphyxia had occurred. Preliminary data from this study have been used to establish the timing of sublethal asphyxial insults accounting for the brain damage in the fetus and newborn.[8] The information presented in the current report represents an expansion of these studies and is particularly concerned with an analysis of the clinical data that might allow the clinician to identify those asphyxial insults that are likely to lead to perinatal brain damage.

Methods

This was a retrospective clinicopathologic study of 208 perinatal deaths between 1976 and 1989 in whom a satisfactory neuropathologic examination was performed. The identification of asphyxia was based on the neuropathologic features characteristic of the effect of this insult on the central nervous system. There was evidence of neuronal or white matter necrosis in 30 cases (14%).

A chart review was carried out. The maternal, obstetric, fetal, labor, delivery, and newborn complications in each case were recorded. Particular attention was paid to the timing of the onset of labor and delivery. Fetal assessments performed in the antepartum period, during labor, and at delivery were reviewed in detail.

Criteria have been established that indicate the approximate time of the asphyxial insult based on the neuropathologic changes in the central nervous system at the time of death.[9] Infants who die during or immediately after an asphyxial insult have structurally normal brains because changes have not had time to occur; survival for ≥18 hours is required before histologic changes become apparent. Table I summarizes these changes, which follow a sequence starting with neuronal necrosis at 18 hours and progressing through microglial and astrocytic activation to the formation of white matter cavities at approximately 96 hours after the asphyxial insult.

The neuropathologist (D.A.R.) had no knowledge of the clinical data during the assessment of the neuropathology. An estimated interval between the initial asphyxial insult and the neuropathologic condition present at the time of death was determined on the basis of the criteria listed in Table I. Consequently, the time at which the asphyxial insult occurred could be placed in one of the antepartum, intrapartum, or newborn periods. Subsequently, the clinical events that occurred before and at the predicted time of brain damage were then examined.

Results

The initial asphyxial insult that led to brain damage was estimated to have occurred in the antepartum period in 17 cases, in the intrapartum period in five cases, and in the newborn period in eight cases. This report examines the 22 cases of fetal asphyxia. Although the neuropathologic criteria do not indicate the time of the asphyxial insult precisely, it was estimated that the antepartum asphyxial insult occurred >48 hours before the onset of labor in three term and eight preterm pregnancies and between 12 and 24 hours before the onset of labor in six preterm pregnancies. Intrapartum fetal asphyxia was estimated to have occurred in two term and three preterm pregnancies.

Table II summarizes the data concerning the timing of the asphyxial insult and the duration of the clinical complications for eight cases from the antepartum asphyxia group in whom the initial asphyxial insult appears to have occurred when the pregnancy was clinically normal. The asphyxial episode occurred >3 days before the onset of labor in three term pregnancies with no clinical risk factors. In three preterm pregnancies the asphyxial episode preceded an antepartum hemorrhage due to premature placental separation by several hours to several days. The asphyxial episode preceded preterm labor in two pregnancies by 12 hours and 7 days.

Table III summarizes the data for nine preterm pregnancies in whom the antepartum asphyxial insult appeared to have occurred during a clinically complicated pregnancy. The pregnancy complications in each case included one or more maternal, obstetric, or fetal com-

plications. A conservative management program was in effect in each case to achieve improved fetal maturity for periods up to 6 weeks before either spontaneous or elective preterm delivery. Fetal surveillance during this period included intermittent fetal heart rate auscultation in five cases and serial biophysical profile and nonstress tests (NST) in four cases. No distinctive abnormality of fetal behaviour was observed at the estimated time of the sublethal asphyxial insult. An abnormal biophysical profile reported in two cases was recorded after the estimated time of the asphyxial insult and central nervous system injury. This sequence is exemplified by the following case.

A 28-year-old obstetric patient, gravida 1, para 0, was admitted to the hospital at 28 weeks' gestation because of moderate preeclampsia. An ultrasonographic diagnosis of growth retardation was made at 30 weeks. At 32 weeks an ultrasonographic examination reaffirmed the diagnosis of growth retardation with decreased amniotic fluid volume. Neuropathologic studies at postmortem examination indicated that the asphyxial insult occurred at this time, i.e., 72 hours before delivery. However, serial NSTs continued to be reactive. A nonreactive NST and an abnormal biophysical profile were first observed on the day of delivery, leading to emergency cesarean section. The 980 gm newborn had a significant metabolic acidosis, pH 7.02 and buffer base 29 mmol/L, and died 10 hours after delivery.

Table IV summarizes the data for five pregnancies in which the asphyxial insult was estimated to have occurred during the intrapartum period. The two term

pregnancies had been uneventful. However, during labor one patient had meconium in the amniotic fluid, and the second patient had a prolapsed cord with a breech presentation. Complications in the preterm pregnancies included antepartum hemorrhage in two cases and pregnancy-induced hypertension in one case. All cases had evidence of clinical fetal distress as expressed by fetal bradycardia, decreased baseline heart rate variability, or decelerations during the latter part of labor. Fetal asphyxia was confirmed in three cases with blood gas and acid-base measurement at delivery. The Apgar scores in these cases were 1 and 1 minute and 1 to 4 at 5 minutes.

Comment

The fetus in each of these 22 pregnancies had experienced, sometime before birth, a "sublethal" asphyxial insult of sufficient severity to cause brain damage but not of such severity to lead to the immediate death of the fetus. The prevalence of "sublethal" asphyxial episodes is not known, but the incidence of neuropathologic abnormalities in this series of perinatal deaths (14%) provides an estimate of the frequency of such asphyxial episodes. Wigglesworth[10] in a recent study of neuropathologic findings in mature stillbirths has reported an incidence of damage to gray matter in 33% of normally formed third trimester stillbirths. It is apparent from current imaging of parenchymal lesions in the newborn, that similar episodes may occur in the fetus, and that these abnormalities may account for motor and cognitive deficits in the surviving children.[11, 12]

Moderate to severe periventricular leukomalacia was observed in 14 of the 22 cases of fetal asphyxia. All cases had some degree of neuronal necrosis in the cerebral cortex, basal ganglia, thalamus, or brain stem. These findings are in keeping with previous descriptions in the literature.[13-16]

Such asphyxial insults may occur at any time during the last half of pregnancy or during the course of labor. Antepartum insults, occurring from 12 hours to 7 days before the onset of labor, accounted for 75% of the cases of fetal asphyxia. The stress of labor with intrapartum fetal asphyxia of sufficient severity to cause neuropathologic abnormalities occurred in 25% of the subjects studied.

These findings indicate that the clinician must anticipate asphyxial insults at any time during the last half of pregnancy before or during labor. This study clearly demonstrates that identification of impending fetal asphyxia and thus timely intervention is hampered by the frequent covert onset of asphyxia and the limitations of current methods of fetal assessment. Thus eight cases of antepartum asphyxia occurred when there were no apparent indicators that the fetus was at risk. Of these, three episodes occurred in uncomplicated term pregnancies and five episodes occurred in preterm pregnancies before the appearance of clinical evidence in either antepartum hemorrhage or preterm labor.

The NST and the biophysical profile are widely acknowledged measures of fetal well-being. However, these noninvasive measurements are intermittent and, in the preterm pregnancy before 28 weeks, they are difficult to interpret. Approximately half of the antepartum asphyxial insults reported in this study occurred in complicated preterm pregnancies during conservative management programs to improve fetal maturity. The clinical observations at the histologically estimated time of the asphyxial insult did not suggest a compromised fetus. The abnormal NST and biophysical profile recorded in two cases were obtained

after the asphyxial insult and central nervous system injury had occurred.

Intrapartum fetal assessment cannot begin until the patient is admitted to the hospital, and certain criteria are met to justify such surveillance. Thus assessment does not begin with the onset of labor in most cases and may only be available for the latter part of labor in some cases. Intrapartum continuous fetal heart rate monitoring provides predictive criteria for fetal asphyxia, although the diagnosis can be confirmed by means of a blood gas and acid-base assessment of fetal blood during labor or at delivery. Such observations were obtained in the five cases in the intrapartum asphyxia group. However, it is likely the sublethal asphyxial insult accounting for the brain damage began before the onset of these observations of clinical fetal distress during labor and the blood gas measures at delivery.

These findings highlight some of the problems for the clinician in the diagnosis of fetal asphyxia at a stage that would permit intervention to prevent the neuropathologic conditions responsible for deficits in children.

Simplified Gram stain interpretive method for diagnosis of bacterial vaginosis

Jessica L. Thomason, MD,[a] Robert J. Anderson, PhD,[b] Sheldon M. Gelbart, PhD,[a] Peter J. Osypowski, MT(ASCP),[a] Nancy J. Scaglione, OGNP,[a] Gamal El Tabbakh, MD,[a] and Janine A. James, MD[a]

Milwaukee, Wisconsin, and Chicago, Illinois

OBJECTIVE: Two methods which only consider bacterial morphotypes and require counting various types of bacteria, for interpreting Gram stains of vaginal secretions for the purpose of diagnosing bacterial vaginosis were previously described. A new interpretative method, which combines clue cells with bacterial morphotypes as diagnostic markers, is offered.

STUDY DESIGN: One hundred twenty patients were tested with the new interpretative method and clinical criteria of bacterial vaginosis as the reference standard.

RESULTS: The new method was found comparable to older methods when all were compared with clinical diagnostic methods. The sensitivity of the clue cell method was 86.1% and the specificity was 92.8%. The predictive value of a positive test was 83.7% for a population with a prevalence of bacterial vaginosis of 30%. The negative predictive value was 94.0%.

CONCLUSION: If clue cells are present and the nonlactobacilli morphotypes exceed lactobacilli morphotypes, bacterial vaginosis can be diagnosed without the need for exact bacterial counts. (Am J Obstet Gynecol 1992;167:16-9.)

Key words: Bacterial vaginosis, Gram stain, diagnosis

Bacterial vaginosis is the syndrome thought to be the most prevalent cause of vaginitis.[1] Several clinical diagnostic criteria, Gram stain methods, and biochemical markers have been developed to aid in diagnosis.[2] Gram stain of vaginal secretions is a relatively rapid, objective, and inexpensive method for diagnosing bacterial vaginosis by identifying the characteristic change in the vaginal flora.[3] It offers the advantage of allowing retrospective diagnosis. The normal vaginal flora consists of a wide variety of bacteria with lactobacilli as a major constituent. In bacterial vaginosis there is a greater than 400-fold increase in anaerobic flora with a diminished proportion of lactobacilli.[2] On Gram stain large gram-positive lactobacilli morphotypes are easily distinguishable from gram-negative organisms, cocci, *Gardnerella*, and other anaerobic bacterial morphotypes.[3] However, the change in proportion of lactobacilli appears to be an early stage in the development of bacterial vaginosis, as evinced by the low specificity of this single observation in wet mount preparations when compared with clinical diagnostic criteria for bacterial vaginosis.[4] In contrast, clue cells, vaginal epithelial cells that are so covered by attached bacteria that the cell borders become obscured, have been shown to be extremely specific for bacterial vaginosis defined by clinical criteria.[2, 4]

Existing Gram stain interpretive methods focus only on quantification of bacterial morphotypes.[3, 5] However, clue cells can also be identified on Gram stains.[6] The purpose of this study was to examine a Gram stain interpretive method involving mere observation of clue cells coupled to identification of predominant morphotype. This new interpretive method was compared with both preexisting methods, Spiegel et al.[3] and Nugent et al.[5] The clue cell method obviates the need for exact counts of various morphotypes and, because of the size of lactobacilli and clue cells, can be read at a magnification of ×400.

Methods

Gram stains were made from the vaginal secretions of 120 consecutive patients previously tested for and found not to have chlamydia (chlamydiazyme, Abbott Laboratories, Abbott Park, Ill.) or gonorrhea (culture, Thayer-Martin Agar, Becton Dickinson, Cockeysville, Md.) attending the Adolescent Pregnancy Program at Sinai Samaritan Medical Center. The mean age of these 120 patients was 16.1 ± 2.4 years, and the mean weeks of gestation was 19.1 ± 3.8. All teens were pregnant and enrolled at their initial obstetric appointment after informed consent was obtained. One slide was prepared for each patient. Commercial Gram stain reagents (Difco, Detroit) were used as instructed by the

manufacturer. Each slide was interpreted by the same individual (P.J.O.) with three different Gram stain criteria.[3, 5] The criteria of Spiegel et al.[3] are described in Table I. Slides were read on a Microstar IV binocular microscope (Reichert, Cambridge Instruments Inc., Buffalo, N.Y.). A technician was selected to interpret the Gram stains, because this would most likely be the situation in a clinical laboratory setting and this is the group that the test is designed for. The criterion of Nugent et al.[5] is described in Table II. For the clue cell method, slides were read at a magnification of ×400 with a thin film of oil and a coverslip used to protect the objective lens. No exact enumeration was made. Bacteria in each field were evaluated simply as to whether lactobacilli morphotypes exceeded other morphotypes, and presence of clue cells was noted. Patients were considered to have bacterial vaginosis by the clue cell method of interpretation if nonlactobacilli morphotypes exceeded lactobacilli in the majority of fields examined and if clue cells were seen in at least two of 20 fields. Vaginal epithelial cells covered with lactobacilli were not considered clue cells. Cell edges had to be completely covered with bacteria to be called clue cells. Both conditions, presence of clue cells and predominance of nonlactobacilli, had to be observed for the Gram stain to be interpreted as bacterial vaginosis.

Patients were also evaluated for bacterial vaginosis by their examining physician (J.L.T., G.E.T., or J.A.J.) with the clinical diagnostic criteria proposed by Amsel et al.[7] Patients were considered clinically to have bacterial vaginosis if three of the following four characteristics were observed: clue cells in wet mount preparations of vaginal secretions, fishlike amine odor upon alkalinization of vaginal secretions with 10% potassium hydroxide, vaginal pH >4.5, and presence of homogeneous discharge that adhered to the walls of the vaginal introitus. The individual who was interpreting Gram stains (P.J.O.) was blinded from the clinical diagnosis. Corrected χ^2 statistics were used to compare the different interpretive methods.

Table I. Spiegel et al.[3] Gram stain interpretation

Morphotypes per field *	*Evaluation*
<1	1+
1-5	2+
6-30	3+
>30	4+

The following morphotypes were counted individually: large gram-positive rods were considered *Lactobacillus* morphotypes, short gram-variable rods were *Gardnerella* morphotypes, and cocci, curved rods, and fusiforms were other morphotypes. The patient was diagnosed as having bacterial vaginosis if *Lactobacillus* morphotypes were <2+, *Gardnerella* morphotypes were 4+, and at least one other morphotype was present.

*Average number of morphotypes per oil immersion field (original magnification, ×1000). Twenty fields were counted.

Table II. Nugent et al.[5] Gram stain interpretation

Score	*Lactobacillus*	*Gardnerella*	*Mobiluncus*
0	4+	0	0
1	3+	1+	1-2+
2	2+	2+	3-4+
3	1+	3+	
4	0	4+	

For the Nugent et al. method, exact morphotype counts were made as for the Spiegel et al. method at a magnification ×1000 but an additional morphotype, crescent rods (*Mobiluncus* morphotypes), was used in place of "other morphotypes." A score was given to each evaluation. The patient was diagnosed as having bacterial vaginosis if the score for all three morphotypes was >6.

Results

Thirty-six patients were found to have bacterial vaginosis by Amsel's clinical criteria. These patients were used as our reference standard as "true" positives. Comparison of Gram stain interpretative criteria to this reference standard is shown in Table III. Thirty-nine patients had bacterial vaginosis by Spiegel et al.'s Gram stain interpretive criteria, only 30 of which were true positive. The Nugent et al. Gram stain interpretive criteria identified 34 patients as having bacterial vaginosis, but only 31 were true positive. The clue cell Gram stain interpretive criteria identified 37 patients as having bacterial vaginosis, but only 31 were true positive. All 30 true-positive results by Spiegel et al. were also positive by Nugent et al. and clue cell interpretive criteria. In addition, both Nugent et al. and clue cell methods identified one additional true positive. The Nugent method had the least number of false-positive results.

Five patients having bacterial vaginosis by Amsel clinical criteria were falsely negative by all three Gram stain interpretive methods. The slides all showed approximately equal numbers of lactobacilli and other morphotypes, with two of the five (40%) showing clue cells. They were all considered intermediate, i.e., point value 4 to 7, by the criteria of Nugent et al. Neither Spiegel et al.'s nor clue cell methods of interpretation have an intermediate classification.

The sensitivities, specificities, and positive and negative predictive values with the clinical criteria of Amsel et al. as the reference standard are shown in Table III. There were no statistically significant differences between any of the three interpretative methods.

Comment

Comparing the three Gram stain interpretation methods to Amsel et al.'s clinical criteria shows that they all give comparable results. Simply screening the Gram stains for predominance of lactobacilli and absence of clue cells or for predominance of nonlactobacilli mor-

Table III. Evaluation of three Gram stain interpretive methods to diagnose bacterial vaginosis* ($N = 120$)

Method	True positive	True negative	False negative	False positive	Sensitivity		Specificity		Positive predictive value		Negative predictive value

Spiegel et al.	30	75	6	9	83.3	6.2	89.2	3.4	76.9	6.7	92.5	2.9
Nugent et al.	31	81	5	3	86.1	5.8	96.4	2.0	91.2	4.9	94.2	2.5
Clue cell	31	78	5	6	86.1	5.8	92.8	2.8	83.7	6.1	94.0	2.6

*Thirty-six women clinically diagnosed with bacterial vaginosis.

photypes and presence of clue cells is much easier than the more exact interpretive criteria outlined by Spiegel et al. and more recently by Nugent et al.[3, 5] The sensitivities of all methods are virtually identical. The Nugent method is probably more specific. Failure to demonstrate significance between the difference in specificities may have been due to small sample size. However, it is questionable whether the small increased specificity justifies the additional requirement to read slides at a magnification of ×1000 and to enumerate morphotypes. The finding that the Spiegel interpretive method had a specificity of 83% and sensitivity of 89% when compared with Amsel criteria is ±4% of the values reported by Eschenbach et al.[8] The clue cell method described should be more easily standardized for practitioners and laboratory personnel. Clinically, this method accounts for the fact that it is simplier to differentiate lactobacilli morphotypes from other types of bacteria. In addition, this simplified method does not require the examiner of the slide to spend large amounts of time to singularly count each various bacterial type involved with this syndrome as is described by other methodologies.[9]

Photomicrographs of Gram stains are not included because excellent photomicrographs showing clue cells and the change in bacterial flora seen in bacterial vaginosis have been published by both Spiegel et al. and Nugent et al.[3, 5] Both groups failed to consider clue cells in their interpretive criteria. Dunkelberg[6] described a method to diagnose bacterial vaginosis (he called it "*Hemophilus vaginalis* vaginitis") on the basis of clue cells "with an overlay of large numbers of small gram negative bacilli and equally dense bacterial population adjacent to the epithelial cells in gram-stained smears." His recommendation was not followed. His description was vague and not easily interpretable. The present report clearly defines exactly what the observer is to look for.

The recommended number of clue cells required to make the diagnosis of bacterial vaginosis is controversial. Eschenbach et al.[8] recommends that greater than 20% of epithelial cells must be clue cells. They claim that with this criterion 19% of patients that meet the Amsel clinical criteria do not have clue cells. However, if any well defined clue cell is used as the criterion, only 1% of patients that meet the Amsel criteria cannot be shown to have clue cells.[4] But both of these reports were based on wet mount observations of clue cells, not Gram stains. The specific recommendation of two fields with any clue cell worked well in this study. Whether this is the optimal number remains to be determined.

Early researchers claimed that clue cells did not correlate with bacterial vaginosis, basing this claim on successful culture of the organism now known as *Gardnerella* as their reference standard.[10] It has become well established that culture for *Gardnerella* does not correlate with clinical diagnosis of bacterial vaginosis.[8] Patients that have *Gardnerella* in their vaginal flora do not necessarily have bacterial vaginosis even when the organism is present in high numbers.[2, 8]

In contrast, clue cells have been shown to be highly sensitive and specific for bacterial vaginosis when clinical diagnostic criteria are used as the reference standard.[4] Including clue cells in the interpretive criteria obviates the need for enumeration of morphotypes, making the interpretation easier. This should allow greater interlaboratory reproducibility. The clue cell Gram stain interpretive criteria contains no intermediate grouping as is the case with the Nugent method because the significance of this group of patients is unknown.

The clue cell method offers a major advantage over other Gram stain interpretative methods for bacterial vaginosis. With this method a magnification ×400 facilitates the scanning of more fields of a patient's slide. Twenty fields at ×400 allows the examiner to view the entire area under the coverslip, which in turn allows the examiner to view a larger sample of the specimen, leaving less chance for error in making a diagnosis. Finally, this methodology takes much less overall labor time when compared to the other methods discussed, whether a clinician or laboratory personnel is involved. With less time used per patient specimen, larger numbers of women could be effectively screened, thereby promoting overall better patient care.

Ethically justified guidelines for family planning interventions to prevent pregnancy in female patients with chronic mental illness

Laurence B. McCullough, PhD,[a] John Coverdale, MB, ChB,[b] Timothy Bayer, MD,[c] and Frank A. Chervenak, MD[d]

Houston, Texas, and New York, New York

OBJECTIVE: This article proposes ethically justified clinical guidelines for family planning interventions to prevent pregnancy in female patients.
STUDY DESIGN: We reviewed literature on family planning and consequences of pregnancy in patients with chronic mental illness and related that literature to ethical principles.
RESULTS: Patients with chronic mental illness are ethically unique because they have chronically and variably impaired autonomy. Existing guidelines and proposals for family planning interventions for mentally retarded patients are shown not to apply to such patients.
CONCLUSION: Three sets of guidelines for three groups of patients, representing the continuum of chronically and variably impaired autonomy, are proposed: (1) a set of guidelines for patients who can achieve thresholds of autonomy, (2) a set of guidelines for patients irreversibly near thresholds of autonomy, and (3) a set of guidelines for patients irreversibly below thresholds of autonomy. These guidelines should contribute significantly to the quality of obstetric and gynecologic care for female patients with chronic mental illness. (AM J OBSTET GYNECOL 1992;167:19-25.)

Key words: Ethics, family planning, chronic mental illness, chronically and variably impaired autonomy

Family planning interventions to prevent pregnancy in female patients with chronic mental illness pose unique ethical challenges to the obstetrician and gynecologist. Respect for the patient's autonomy, a central ethical principle, is especially difficult to implement in the clinical setting of chronic mental illness. Whereas the definition of chronic mental illness is still evolving, established criteria include the diagnosis of a major

mental disorder such as schizophrenia, major affective disorder, or personality disorder; disabilities in social, physical, or employment-related areas; and a prolonged duration (usually ≥2 years) of treatment and illness.[1] Patients with chronic mental illness differ from the mentally retarded in a manner that ethics is uniquely qualified to identify and assess. Hence, existing guidelines and previous work on the ethics of family planning for mentally retarded patients are not conceptually adequate for patients with chronic mental illness. Guidelines of The American College of Obstetricians and Gynecologists for mentally handicapped patients[2] appear to treat informed consent issues in terms of a dichotomy between those capable of consent and those not capable of consent. Patients with chronic mental illness often fall between the extremes of this dichotomy and thus must be treated as an ethically and clinically distinct group.

To this end, we introduce and develop the concept of chronically and variably impaired autonomy as uniquely characterizing most patients with chronic mental illness. On the basis of this concept we present ethically justified, clinically applicable guidelines for family planning interventions for patients with chronic mental illness. These clinical guidelines include respect for the autonomy of these patients and attempts to restore autonomy when it is chronically and variably impaired. Women with chronic mental illness are at risk for not receiving adequate family planning and other obstetric and gynecologic services. Adopting the proposed guidelines may help to improve the quality of obstetric and gynecologic care of these women.

Clinical considerations

Chronic mental illness. Up to 2.4 million people are seen in community mental health clinics[3] whereas schizophrenia itself has a lifetime prevalence of about 1%.[4] Many of these patients are homeless and recidivistic, and their mental disability may limit their ability to seek local, state, or federal assistance such as housing, food stamps, rehabilitation, or protective services.[5] These patients also often have unrecognized physical illness,[6,7] and the course of illness may be complicated by substance abuse, including alcohol abuse, more frequently than chance would predict.[8,9] They may present to family planning clinics or gynecologic offices when brought by family members or referred by psychiatrists for contraception. Alternatively, patients may be referred when already hospitalized for an unrelated problem, or contraceptive issues may be identified when the patient presents for management of pregnancy.

Although a heterogeneous population, patients with schizophrenia may suffer from delusions, prominent hallucinations, or incoherence.[10] Alternatively, patients with bipolar mood disorder who are in a manic state demonstrate flight of ideas, grandiose and overgeneralized thinking, and easy distractibility.[11] Patients' ability to process information may also be limited by cognitive and attentional deficits.[12] Moreover, cognitive impairment, poor judgment, affective instability, and impulsivity are likely to result in behaviors that include unsafe sexual practices and intravenous drug use.[13] Thus patients with chronic mental illness are at risk for human immunodeficiency virus infection[13] and other sexually transmitted diseases, as well as for unwanted pregnancies.[14-16] They are also unlikely to comply with a recommendation of abstinence as a family planning strategy.

Maternal risks. Psychosis itself may directly affect maternal health when patients act on delusions or on auditory hallucinations.[17,18] Patients with chronic mental illness have also been found to be significantly less likely to have attended prenatal clinic appointments.[19] Psychotic denial of pregnancy, although a rare phenomenon, may relate to a failure to obtain prenatal care, as well as to postpartum emotional disturbance in the mother and precipitate or unassisted delivery.[20] For all pregnant women there is a small added risk of first admission for psychosis during pregnancy and within 3 months post partum.[21] A history of psychosis might therefore predispose to mental health complications for women during pregnancy.[22,23]

Fetal risks. Factors that may negatively influence pregnancy outcomes among this population include the possible effect of psychiatric medication and illicit drug use on the fetus.[24-26] Results have been mixed, however, regarding the relationship between mental illness and obstetric outcome. In two controlled studies no relationship was found.[27,28] On the other hand, one prospective study found an increased incidence of fetal and neonatal deaths among offspring of schizophrenics when compared with a closely matched control group.[29] In another controlled study, prematurity, lower birth weight, and lower apgar scores were found to relate to the severity and chronicity of mental illness.[30] Outcome can be improved, however, by close prenatal observation, including psychiatric hospitalization, which allows for appropriate obstetric intervention.[31]

Risks to possible future children. Possible future children may be at increased risk for a variety of chronic mental illnesses.[32-34] In schizophrenia, for example, the risk that a child of a schizophrenic parent will have schizophrenia has been shown to be increased. This increased risk is multifactorial and genetic, and environmental influences may account for it.[35-37] Children of the chronically mentally ill are frequently not raised by their mothers,[16] which would expose such children to the effects of early separation from an original parent. Little is known about whether childbearing pro-

tects the health of mentally ill women or predisposes them to mental illness.[38-40]

Decision-making about health care by the chronically mentally ill

The psychiatric impairments of these patients imply that they can and do experience difficulty in making decisions about their health care, including family planning interventions to prevent pregnancy. Decision-making about health care can be understood to involve the following process on the part of the patient, a process in which each step presumes successful completion of its predecessors:

1. The patient attends to the information disclosed to him or her by the physician.
2. The patient absorbs, retains, and recalls the information disclosed.
3. The patient appreciates that this information has significance in the patient's life and the lives of others (e.g., parents, spouse, partner, the fetus being taken to term, or future child). This requires that the patient understands that decisions about health care have consequences for the future and reasons well enough to connect present decisions with future possible consequences. This can be called *cognitive understanding*[40a] and requires some nominally intact cognitive abilities.
4. The patient evaluates those consequences on the basis of her values and beliefs. This can be called *evaluative understanding*[40a] and requires some nominally integrated sense of oneself.
5. The patient at some meaningful level expresses or communicates both cognitive and evaluative understanding.
6. The patient should be able at some meaningful level to express or communicate a decision based on such understanding.

This account differs from the usual account of the informed consent process, which is typically understood to involve disclosure of an adequate amount of information to the patient, understanding of that information by the patient (step 3), and a voluntary decision by the patient (step 6). Appelbaum and Grisso,[41] for example, identify four steps: "communicating choices," which blends without distinguishing steps 5 and 6; "understanding relevant information," which presupposes step 2 and is similar to step 3; "appreciating the situation and its consequences," which is also similar to step 3; and "manipulating information rationally," which is similar to step 4. Their approach does not clearly distinguish cognitive from evaluative understanding and ignores altogether step 1, a crucial consideration in the care of patients with chronic mental illness. We will comment on each of these six steps in some greater detail.

Steps 1 and 2 are included because patients with a history of chronic mental illness may have problems during the disclosure of information. These problems can result from factors such as attentional deficits that are associated with the patient's illness (e.g., auditory hallucinations or paranoia that may distract the patient from attending to, absorbing, recalling, or retaining what is disclosed).

Steps 3 and 4 are included to identify two related but distinct aspects of understanding. This distinction is important for informed consent involving patients with chronic mental illness because such illness can affect cognitive and evaluative understanding independently and in different ways. Cognitive understanding can be adversely affected by cognitive deficits. These tend to involve processing information (step 3) more than memory (step 2). For example, difficulties with step 3 may arise when patients use the mechanism of denial excessively in relation to their likelihood to engage in sexual intercourse.[14] Evaluative understanding can also be adversely affected. A patient's values and the ability to base decisions on them can be disrupted by paranoid or grandiose ideas, delusions, or affective disturbances such as significant depression. For example, patients may have a psychotic paranoia about oral contraceptives. Patients may also evaluate their ability to be adequate parents in an unrealistically positive way.[42-44]

Steps 5 and 6 are included because chronic mental illness frequently involves disrupted ability to express or communicate cognitive or evaluative understanding. This disruption can result from incoherence, circumstantiality, tangentiality, and loose associations.

Chronically and variably impaired autonomy

The obstetric, pediatric, and psychiatric outcomes described include the possibility of significant obstetric and mental health complications, possible adverse consequences in child development, and potential adverse consequences for patients with chronic mental illness and their partners. The decision-making process for these patients includes many factors that can impair or disrupt that process. It is a natural tendency for physicians, given these circumstances, to approach the family planning interventions for chronically mentally ill, fertile, sexually active female patients in a "paternalistic" fashion. By "paternalistic" we mean that the physician is inclined to strongly influence or even take over the patient's autonomous decision-making process to avoid significant adverse consequences.

Recall that autonomous decision-making may usefully be conceptualized in terms of the six-step decision-making process described. In discussing those six steps, we noted that for patients with chronic mental illness one or more of the capacities described is likely to be impaired and that this is a permanent feature of the

mental illness. In addition, this impairment may vary for each of the steps to differing degrees, including differing degrees over time in the same patient. We term this clinical ethical phenomenon *chronically and variably impaired autonomy.*

This phenomenon uniquely applies to the patient with chronic mental illness. In particular, it does not apply to severely and profoundly mentally retarded patients. This is because their loss of autonomy is nearly complete and does not vary. Nor does chronically and variably impaired autonomy apply to mildly and moderately mentally retarded patients, because they can participate in the consent process. This dichotomy is reflected in the guidelines of The American College of Obstetricians and Gynecologists.[2] The autonomy of patients with chronic mental illness typically falls along a continuum between those two extremes and thus must be treated separately.

Put another way, a chronically mentally ill patient may at any one time be above a threshold for one capacity (e.g., to attend to what is being said or cognitive understanding), while being below a threshold for another capacity (e.g., evaluative understanding or communicating a decision based on cognitive and evaluative understanding). That patient's decisions are indeed substantially autonomous,[45] but only in some respects and not in others, with variation over time.

We share the usual presumption, in ethics and law, that the patient possesses adequate decision-making capacity.[45] This capacity may seem, at first, to be called into question by the chronically and variably impaired autonomy. However, the variability of chronically and variably impaired autonomy calls into question both that the capacity to make decisions is always absent for such patients and that attempts at informed consent can be justifiably omitted. This helps to illuminate further the unique character of chronically and variably impaired autonomy, and one of its important implications—these patients should not be judged uniformly to be without decision-making capacity.

Another implication of chronically and variably impaired autonomy is that strategies of "weak paternalism" cannot be invoked either. Weak paternalism involves an intervention taken to benefit a patient who has fallen below the threshold of autonomous decision-making. Weak paternalism, however, cannot meaningfully be invoked on the basis for intervening in such a patient's decision-making, because there is some substantial, if variable, autonomy that will be seriously violated in the process. Nor can strong paternalism—the violation of the patient's autonomy for his or her good—be justified for the same reason: There is some substantial, if variable, autonomy that will be seriously violated in the process. Some third ethically justified response is called for, and we turn now to the task of identifying such a response.

Ethically justified guidelines

Chronically and variably impaired autonomy, then, means that there are always some one or more aspects of impaired autonomy in patients with chronic mental illness. It is important to recognize that the variable aspects of impaired autonomy may be responsive to ameliorative interventions, because this clinical reality serves as the basis for a series of ethically justified guidelines for family planning interventions to prevent pregnancy in female chronically mentally ill patients. These guidelines thus go beyond the recent guidelines of The American College of Obstetricians and Gynecologists[2] and the literature on mentally retarded patients,[46] which do not take account of the phenomenon of chronically and variably impaired autonomy.

A set of guidelines for patients who can achieve thresholds of autonomy

The first-line response should therefore be to treat chronically and variably impaired autonomy, with the aim of restoring all aspects of impaired autonomous decision-making to a degree at or above a nominal threshold. Each of these aspects, described in the six steps listed, has its own threshold. These thresholds are patient and decision specific. Substantially autonomous decision-making occurs when the patient can exercise all of the capacities at or above their thresholds with respect to the decision at hand (e.g., to use contraceptive barriers).

In some cases patients with chronic mental illness will meet or exceed all of these thresholds. Since clinical judgment about such matters concerns the patient's mental illness and its effects on decision-making capacity, the involvement of a psychiatrist in implementing the guidelines we propose may be very helpful. Securing such involvement in most hospital settings should not be difficult, inasmuch as consultation-liaison psychiatric services are generally available. In other settings, especially family planning centers, appropriate liaison should be established with psychiatric centers, including community mental health programs.[47]

Restoring chronically and variably impaired autonomy involves the following steps:

a. Identify those aspects (steps 1 to 6 as listed previously) of autonomous decision-making that are chronically impaired.
b. Document the history of the variability of impairment, with particular attention to factors that exacerbate that impairment (e.g., psychosocial stressors, drug abuse, going off medication, or medical illness).
c. Identify and implement interventions aimed at improving impaired aspects of autonomous decision-making to a degree at or above the threshold (e.g., medication for loose associations, inten-

sive, repeated provision of information,[48] and removal of psychosocial stressors).

d. Implement the six-step decision-making process described. When the patient's decision-making capacities are at or above their thresholds, respect for the patient's autonomy is meaningful and therefore justified. In such cases the patient is capable of participating in the six-step decision-making process described. In short, such patients are capable of participating in the informed consent process.

A set of guidelines for patients irreversibly near thresholds of autonomy

Sometimes efforts to ameliorate chronically and variably impaired autonomy will not succeed, but the patient is nonetheless near thresholds for substantially autonomous decision-making as a result of the interventions just described. Such patients may meet some thresholds but not others. Simply deciding for such patients what is to be done may impose on the patient values different from those held by the patient, a subtle form of paternalism. Chronically and variably impaired autonomy does not in all cases necessarily imply that such values are unknown or unknowable to the physician. They may have been expressed or utilized by the patient (e.g., in step 4, 5, or 6 of the decision-making process described). The patient's values are therefore, in principle, available as the basis for a response to chronically and variably impaired autonomy irreversibly near but not at thresholds for substantially autonomous decision-making. A patient irreversibly near the thresholds for decision-making can at least assent to medical care and can do so meaningfully if the care plan implemented respects her values.

The strategy of this response is to present alternatives to the patient that are reliably judged to be consistent with her values and ask her to select among them. This second strategy for managing chronically and variably impaired autonomy involves the following:

a. Carefully document the patient's expressed values and beliefs related to reproduction.
b. To further identify the patient's values ask her what is important in her life regarding the decision that needs to be made. For example, what are the patient's feelings about being able to successfully prevent conception, her ability to complete a pregnancy safely, her ability to rear a child?
c. It may be useful to make inquiries of the family's perspective, as well as that of the parents, sexual partner, or spouse, since their insights may be valuable. This should be done only with the agreement of the patient. Family members may also have a vested interest in the outcome, especially when it is the family that has requested family planning intervention. Patients should be protected from undue pressure from family members. When there is undue pressure, the patient should be provided with an opportunity to discuss the issues independently of the family.
d. Identify alternatives (including doing nothing) that are consistent with the patient's values and beliefs.
e. Present these alternatives and ask the patient for her choice among them.

A set of guidelines for patients irreversibly below thresholds of autonomy

Sometimes efforts to bring a patient to or near thresholds for substantially autonomous decision-making fail. Such patients are irreversibly substantially below one or more thresholds. They may therefore be irreversibly below all six thresholds. In the literature, the scope of ethical concern is typically expanded beyond the patient's interests to include the interests of possible future children and social costs.[49, 50] How should each of these three factors shape clinical ethical judgment?

The patient's interests. The interests of the patient concern whether pregnancy can be reliably judged to pose significant mental health and physical benefits and risks to the patient. These risks were discussed at the beginning of this article. The mental health and physical risks discussed may be serious (e.g., disruption of psychiatric treatment or self-destructive behavior), but this is not always the case. Fewer still of these risks are irreversible. Mental health risks brought on by pregnancy can be addressed through rigorous biopsychosocial interventions, as can risks to physical health. It is rarely the case that those risks are predictable with reliability, even in patients with documented history of the occurrence of such risks in a prior pregnancy.

The justification for weak paternalism rests on beneficence-based grounds, namely, to avoid predictable irreversible and serious harm to the patient. If this interpretation of the risks of pregnancy for patients with chronic mental illness is correct, these grounds are, as a rule, not satisfied. Thus a paternalistic response to patients without decision-making capacity (i.e., to simply make decisions for them) is not ethically justified.

Risks to possible future children. The risks to possible future children involve the ethical issues of harm to others than the patient. Those risks involve both genetic and social risks. There are some circumstances in which a possible future child is at significant risk for genetic mental illness (e.g., schizophrenia). Schizophrenia is certainly a serious disease, and there is some intuitive appeal to saying the children born with schizophrenia to two parents with the disease might well be better off having never existed. This intuition, in our view, rests on a contended concept, namely, wrongful life. This is the concept that life under certain circum-

stances is worse than being dead.[51] The problem here is that being dead is not a benefit to someone, because there is no "someone" to be benefited. Thus this intuition fails to be conceptually well grounded.

There are social risks to the children of one or two parents with chronic mental illness. These range along a continuum from disrupted or even impaired development to court-ordered removal from the home. These risks may be reversible over time and unpredictable in many cases. Thus serious irreversible social risks to such children are difficult to predict with certainty or even high probability. If the preceding analysis is correct, making reproductive decisions for these patients cannot be justified on the basis of avoiding harm to possible future children.

Social costs. Social costs, however, of pregnancy, birth, and child rearing by women with chronic mental illness do exist. The ethical issue here is whether society can reasonably invoke a justice-based claim to avoid such costs. Society has declined to do so thus far. There is a good reason for this policy. These women are not the only ones at risk for incurring social costs to society from their reproductive decisions. Teenage women and men, for example, constitute a group whose reproductive decisions cause considerable social costs, yet no attempt is made to restrict their reproductive decisions. Picking out only women with chronic mental illness for restriction of reproductive decisions because of social costs would therefore constitute arbitrary discrimination and would be patently unjust. Picking out all women whose reproductive decisions involve social costs would constitute wholesale violation of their constitutional and civil rights, the right to privacy in particular, which is also patently unjust. Thus appeals to avoiding harm to society cannot be justified.

The social costs to parents, spouses, and sexual partners of patients with chronic mental illness may be legitimate considerations. For example, the strong preference of parents who bring the patient for treatment not to be responsible for rearing a grandchild are understandable. However, harm to these legitimate interests is not inevitable, inasmuch as other alternatives are available (e.g., should she become pregnant, the woman raises her child by herself or places her child for adoption). The strong preference of a husband or sexual partner to avoid a pregnancy for the patient can be readily satisfied by his undertaking appropriate measures to ensure his own sterility. Thus harm to his legitimate interests is not inevitable either.

When appeals to paternalism and harm to others cannot succeed, there is no ethical justification for overriding contraceptive choices. The second set of guidelines presented here should therefore be followed, with two considerations.

First, it is not justified to force surgical sterilization on patients whose autonomy is irreversibly lost or to coerce or manipulate them into accepting surgical sterilization, especially since there is now an effective, long-term, implantable, reversible contraceptive device (Norplant).[52]

Second, contraceptive interventions need to be effective, given the consequences of unwanted pregnancies in this population of patients. Because of compliance problems with oral contraceptives,[3] this method of contraception might not be effective in this population. Barrier techniques will be even less effective. By contrast, the Norplant device is significantly more likely to be effective.[52] It has the additional advantage of less serious risks of morbidity associated with long-term use.

The Norplant device must be implanted and removed by a surgical procedure. This factor is ethically significant, because of the potential for abuse. That abuse would take the form of the physician refusing a request by a chronically mentally ill patient to insert or to remove it. Because, as we have shown, appeals to paternalism or harm to others cannot succeed, there is no ethical justification for refusing the patient's request to remove a Norplant device.

In conclusion, patients with chronic mental illness constitute a particularly vulnerable group of patients, with respect to access to gynecologic care and to dehumanization. At the same time such patients constitute an ethically and clinically unique group in terms of autonomy. The proposed guidelines respect the autonomy of these patients and we believe, if adopted, would serve as powerful antidotes to both of these problems and thus contribute significantly to the quality of obstetric and gynecologic care for female patients with chronic mental illness.

A prospective, controlled multicenter study on the obstetric risks of pregnant women with antiphospholipid antibodies

Henk J. Out, MD,[a, b] Hein W. Bruinse, MD,[a] Godelieve C.M.L. Christiaens, MD,[a] Marja van Vliet,[b, c] Philip G. de Groot, PhD,[c] H. Karel Nieuwenhuis, MD,[c] and Ronald H.W.M. Derksen, MD[b]

Utrecht, The Netherlands

OBJECTIVES: A prospective, controlled multicenter study was performed to estimate the obstetric risks of antiphospholipid antibodies (the lupus anticoagulant and anticardiolipin antibodies). In addition, the risks of prior thrombosis, obstetric history, systemic lupus erythematosus, and high-dose prednisone treatment were evaluated.

STUDY DESIGN: After screening for antiphospholipid antibodies in patients with lupus erythematosus or women with prior fetal loss(es), 59 subsequent pregnancies with and 54 without these antibodies were followed.

RESULTS: The presence of the lupus anticoagulant and a history of at least three spontaneous abortions could predict fetal loss ($p = 0.032$ and 0.001, respectively). In live born infants, a low birth weight could be predicted by the presence of anticardiolipin antibodies ($p = 0.034$), prior intrauterine fetal death ($p = 0.025$), and treatment with high-dose prednisone ($p = 0.002$). No relationships were seen between antiphospholipid antibodies and small-for-gestational-age newborns and pregnancy-induced hypertension or preeclampsia. The disappearance of antiphospholipid antibodies during pregnancy was not correlated with live birth.

CONCLUSION: It is concluded that the presence of antiphospholipid antibodies is a risk factor for adverse pregnancy outcome. (Am J Obstet Gynecol 1992;167:26-32.)

Key words: Lupus anticoagulant, anticardiolipin antibodies, pregnancy outcome, systemic lupus erythematosus

In the last decade antiphospholipid antibodies, notably the lupus anticoagulant and anticardiolipin antibodies, have received much attention. Their presence has been associated with prior fetal loss, thrombosis, and thrombocytopenia in retrospective reports.[1-3] These correlations have been described in patients with systemic lupus erythematosus, lupuslike disease, and fetal loss without underlying disease.[4, 5] In patients with antiphospholipid antibodies, fetal loss is generally accompanied by placental thrombosis. However, the pathogenetic potential of these antibodies has not been demonstrated.[6]

There are no large-scale studies evaluating the obstetric risks for pregnant women with antiphospholipid antibodies in a prospective, controlled study. However, on the basis of studies on small series or case reports, it has become current practice to offer some kind of treatment. Successes have been claimed in favor of a therapy that includes high-dose prednisone,[7, 8] but its benefits are also controversial.[9] Other successful treatments reported include subcutaneous heparin or low-dose aspirin.[9, 10]

The need for large prospective, controlled studies in pregnant women with antiphospholipid antibodies is universally recognized.[11, 12] In this study we prospectively evaluated the risks of lupus anticoagulant and anticardiolipin antibodies (both level and isotype) on pregnancy outcome in 59 pregnancies complicated by antiphospholipid antibodies compared with 54 control pregnancies. We also estimated the obstetric risks of systemic lupus erythematosus, lupuslike disease, prior adverse pregnancy outcomes, history of thrombosis, and inclusion of high-dose prednisone in the treatment regimen.

Material and methods

Patients. From June 1987 women who wished to conceive and who were from risk groups were screened for the presence of antiphospholipid antibodies to identify eligible patients for this study. Patients were obtained from all over the country. Risk groups included patients with systemic lupus erythematosus according

to American Rheumatism Association-criteria[13]; patients with lupuslike disease (fewer than four criteria); and patients with at least three unexplained spontaneous abortions before 12 weeks of gestation or at least one intrauterine fetal death after 12 weeks not caused by infection, abruptio placentae, apparent congenital malformations, or chromosomal abnormalities. In all patients with at least three spontaneous abortions hysterosalpingography was performed to exclude uterine malformations. A total of 264 patients were screened, including 61 with systemic lupus erythematosus, 33 with lupuslike disease, and 170 with prior adverse pregnancy outcomes. Antiphospholipid antibodies were found in 115 patients (44%), including 29 with both lupus anticoagulant and anticardiolipin antibodies (25%), one with lupus anticoagulant only (1%), and 85 with anticardiolipin antibodies only (74%, see *Samples and assays*). Fifty-two of 115 patients with antiphospholipid antibodies (45%) subsequently had 59 pregnancies (group A). Of these, 19 were characterized by both lupus anticoagulant and anticardiolipin antibodies, one by lupus anticoagulant only, and 39 by anticardiolipin antibodies only. Of 149 women without antiphospholipid antibodies after screening, 54 had a subsequent pregnancy (36%, group B). In group A, 10 patients had experienced a prior thrombosis (19%) compared with four patients in group B (7%).

Treatment. Treatment, including high-dose prednisone (≥40 mg), was given in 11 patients. Of these, four received prednisone alone, three received prednisone plus low-dose aspirin (80 mg), and four received prednisone plus 2 × 5000 IU regular heparin subcutaneously. All but one had medium- or high-positive levels of anticardiolipin antibodies or lupus anticoagulant. Two patients with systemic lupus erythematosus in remission received prednisone for earlier activity and one as treatment of a lupus exacerbation. In all other patients treatment was given prophylactically because of the presence of antiphospholipid antibodies. Other treatments in group A included 80 mg aspirin in 16 and 2 × 5000 IU heparin given subcutaneously in three patients. In 29 pregnancies from group A no treatment was given. Treatment was given as soon as pregnancy was confirmed by ultrasonography and was continued at the same dose until 6 weeks postpartum. In patients using heparin, oral anticoagulants were given between 16 and 36 weeks of gestation instead of the heparin. In patients with medium or high levels of anticardiolipin antibodies or lupus anticoagulant allocation of treatment between 40 mg prednisone plus 80 mg aspirin versus aspirin alone, or between 40 mg prednisone plus 2 × 5000 IU subcutaneous regular heparin versus heparin alone in patients receiving oral anticoagulants because of prior thrombosis, was initially intended after randomization. However, because 28 of the 32 pregnant women eligible for randomization were reluctant to use high-dose prednisone because of potential side effects, only four were randomized.

Samples and assays

Samples. In addition to the samples obtained for initial screening, monthly blood samples from 19 of 20 patients with lupus anticoagulant and 22 of 31 patients with medium- or high-positive levels of anticardiolipin antibodies after screening were collected during pregnancy and in the postpartum period (median eight samples, range 1 to 15). Samples from patients seen in hospitals other than in University Hospital of Utrecht were sent by mail and stored at −70° C within 24 hours. All assays were performed in this hospital.

Blood samples for the determination of lupus anticoagulant were taken by venipuncture into a 0.1 volume of 3.8% trisodium citrate. Platelet-poor plasma was prepared by centrifuging the blood twice at 4° C at 2000*g* for 15 minutes. Blood samples for the preparation of serum for determinations of anticardiolipin antibodies were collected by venipuncture into glass tubes. The blood was allowed to clot at room temperature for 2 hours and centrifuged at 2000*g* for 10 minutes to obtain serum.

Lupus anticoagulant. Three lupus anticoagulant assays were done as described previously[14]: (1) a partial thromboplastin time with a 1 : 1 mixture of patient and pooled normal plasma with thromboplastin derived from human brain, (2) the partial thromboplastin time of test plasma on dilution of thromboplastin, and (3) kaolin clotting time index, calculated from the kaolin clotting time of control and test plasma, mixed at different ratios. Lupus anticoagulant was considered to be present when at least two assays were positive.

Anticardiolipin antibodies. Anticardiolipin antibodies immunoglobulin G and immunoglobulin M were measured by enzyme-linked immunosorbent assay as described earlier[14] in a 1 : 100 serum dilution. The Kingston Antiphospholipid Antibody Study Group standards were included on all enzyme-linked immunosorbent assay plates to establish cutoff levels between high-, medium-, and low-positive and normal levels, according to the second anticardiolipin standardization exercise.[15]

End points. The end points of this study were fetal death, birth weight, the occurrence of small-for-gestational-age (SGA) newborns with a birth weight below the 10 percentile according to Kloosterman curves corrected for sex and parity,[16] pregnancy-induced hypertension defined as a diastolic pressure of ≥90 mm Hg after the twenty-fourth week of pregnancy without preexisting hypertension, and preeclampsia defined as pregnancy-induced hypertension plus proteinuria of ≥0.5 gm/L.[17] Active lupus nephritis was regarded to be present when, apart from proteinuria or an elevated

Table I. Patient characteristics and pregnancy outcome in 59 pregnancies of patients with antiphospholipid antibodies (group A) and 54 pregnancies of patients without these antibodies (group B)

	Group A	*Group B*
Patients (No.)	52	54
No. of pregnancies	59	54
Systemic lupus erythematosus (n = 37)	29	8
Lupuslike disease (n = 12)	7	5
Prior adverse pregnancy outcome (n = 64)	23	41
At least 3 spontaneous abortions	11	13
At least 1 intrauterine fetal death	9	14
Both spontaneous abortions and intrauterine fetal death	3	14
Outcome		
Spontaneous abortions (n = 15)	7 (12%)	8 (15%)
Intrauterine fetal death (n = 10)	7 (12%)	3 (6%)
Live infant (n = 88)	45 (76%)	43 (79%)
Gestational age* (wk, mean ± SD)	36.9 ± 3.6	38.7 ± 1.6
Birth weight* (gm, mean ± SD)	2665 ± 945	3090 ± 605
No. of children <10th percentile*	11 (24%)	9 (21%)
No. of pregnancies <37 wk*	21 (36%)	3 (7%)
No. of pregnancies with pregnancy-induced hypertension or preeclampsia	10 (22%)	10 (23%)
No. of cesarean sections because of fetal distress	14 (31%)	5 (12%)
Mean gestational age (wk)	33.5	36.6

Fetal loss was predicted by lupus anticoagulant (p = 0.032) and at least three spontaneous abortions in the past (p = 0.001). Low birth weight was significantly associated with a history of intrauterine fetal death (p = 0.025), presence of anticardiolipin antibodies (p = 0.034), and treatment with high-dose prednisone (p = 0.002). Statistical analysis was performed with stepwise multiple and logistic regression.

*Of live infants.

serum creatinine level, extrarenal symptoms suggestive of active disease or an active urine sediment were present.

Statistics. Statistical analysis was performed with Fisher's exact test and stepwise multiple and logistic regression with the statistical package SPSS/PC+ version 3.1 (SPSS, Chicago) and BMDP, version 1987 (BMDP, University of California, Berkeley), to determine the risks of lupus anticoagulant and anticardiolipin antibodies (both level and isotype), systemic lupus erythematosus, lupuslike disease, at least three spontaneous abortions in the past, at least one prior intrauterine fetal death, high-dose prednisone treatment, and a history of thrombosis on the end points, considering all pregnancies (n = 113) as a whole. This technique was chosen because it accounts for the influence of overlaps between variables.

Results

Pregnancy outcome

Fetal loss. In group A, seven spontaneous abortions (12%) and seven intrauterine fetal deaths (12%) occurred versus eight abortions (15%) and three stillbirths (6%) in group B (Table I). Fetal loss was predicted by the presence of lupus anticoagulant (p = 0.032) or a history of at least three spontaneous abortions (p = 0.001) and not by anticardiolipin antibody level or isotype, a history of thrombosis, or the presence of systemic lupus erythematosus or lupuslike disease. The 20 pregnancies with lupus anticoagulant ended in three spontaneous abortions (15%) and four intrauterine fetal deaths (20%), and the 33 pregnancies of patients with at least three spontaneous abortions in the past resulted in 10 spontaneous abortions (30%) and four intrauterine fetal deaths (12%, Fig. 1). All placentas from lupus anticoagulant–positive pregnancies ending in intrauterine fetal death demonstrated signs of thrombosis or infarction. In the placentas from the three stillbirths in group B, no signs of thrombosis or infarction were found. Of 58 patients from group A with anticardiolipin antibodies, seven abortions (12%) and 7 intrauterine fetal deaths (12%) occurred. In the 11 patients treated with high-dose prednisone, one spontaneous abortion (9%) and three intrauterine fetal deaths (27%) occurred, versus two spontaneous abortions (11%) and two intrauterine fetal deaths (11%) in the 19 patients treated with low-dose aspirin or heparin (p = 0.310, Table II). In the 29 patients from group A without any treatment, four spontaneous abortions (14%) and two intrauterine fetal deaths occurred (7%, Table II).

Birth weight and gestational age of live infants. The relationship between birth weight and gestational age at delivery of live infants is shown in Fig. 2. Mean birth weight and gestational age were 2665 gm and 36.9 weeks in group A and 3090 gm and 38.7 weeks in group B. Birth weight was significantly lower in patients with anticardiolipin antibodies (mean weight 2660 gm, p = 0.034), prior intrauterine fetal death (mean weight of 2765 gm after one stillbirth, 2610 gm after two or more, p = 0.025) and in patients treated with high-dose prednisone (mean weight 1870 gm, p = 0.002) compared with patients without these characteristics. Mean birth weight and gestational age in patients treated with low-dose aspirin or heparin were 2565 gm and 36.5 weeks (Table II).

Twenty-one pregnancies (36%) in group A and three

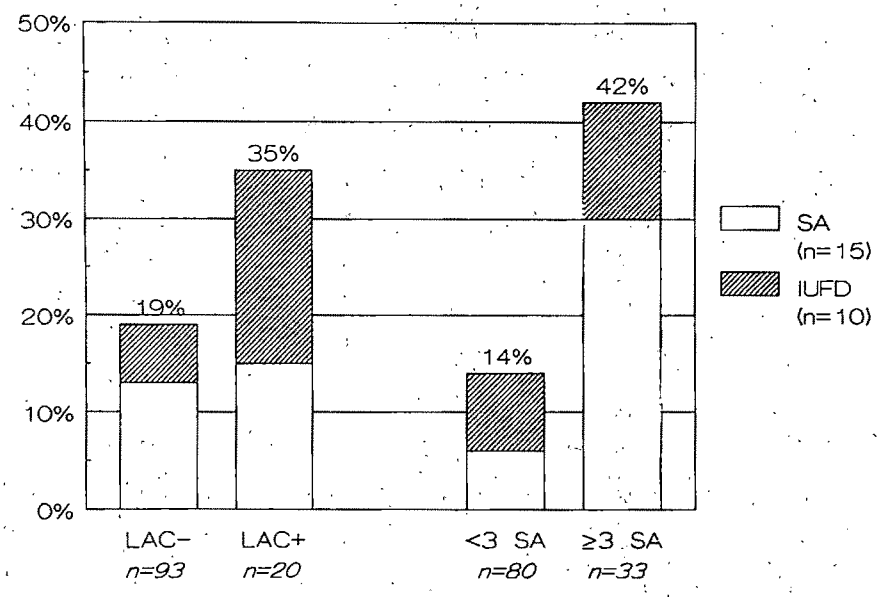

Fig. 1. Fetal loss rates in women with (n = 20) or without (n = 93) lupus anticoagulant and in women with at least three prior spontaneous abortions (*SA*, n = 33) or less (n = 80). Lupus anticoagulant and history of at least three spontaneous abortions predicted fetal loss (p = 0.032 and p = 0.001, respectively). Note that increased fetal loss rate in women with lupus anticoagulant is due to intrauterine fetal death *(IUFD)* after 12 weeks of gestational age, in contrast to increased fetal loss rate in women with at least three previous spontaneous abortions, who primarily aborted in first 12 weeks of pregnancy.

(7%) in group B ended before 37 weeks of gestation ($p < 0.001$). Fourteen cesarean sections (31%) in group A and five (12%) in group B were performed because of fetal distress (p = 0.032). The mean gestational age at time of cesarean section was 33.6 weeks in group A and 36.6 weeks in group B.

SGA. Eleven children in group A (24%) and nine in group B (21%) were SGA, which could not be predicted by any of the variables.

Pregnancy-induced hypertension or preeclampsia. Ten patients in group A (22%) had pregnancy-induced hypertension or preeclampsia versus 10 in group B (23%). None of the evaluated variables could predict these complications. None of the lupus patients developed lupus nephritis.

Complications of treatment. In the 11 patients treated with high-dose prednisone, a cushingoid face was present in all, severe striae in one, and acne in four. No vertebral collapses occurred. In one patient treated with subcutaneous heparin an abscess developed at the injection site. No side effects of low-dose aspirin were seen nor were any drug-related neonatal complications.

Follow-up of antiphospholipid antibodies during pregnancy. From 19 evaluated lupus anticoagulant–positive pregnancies, lupus anticoagulant disappeared during pregnancy in eight patients with two fetal losses. In 11 pregnancies, with persistently present lupus anticoagulant, three fetal deaths occurred.

From 22 evaluated pregnancies with medium- or high-positive lupus anticoagulant anticardiolipin antibody levels after screening, three patients reached low or negative levels without fetal losses. Fourteen live births and five fetal losses occurred in 19 pregnancies with persistently medium- or high-positive anticardiolipin antibody levels. There was no significant association between the disappearance of lupus anticoagulant (p = 0.664) or anticardiolipin antibodies (p = 0.441) and live birth.

Comment

This is the first prospective controlled study that evaluated the obstetric risk of antiphospholipid antibodies. With a statistical analysis technique accounting for the influence of overlap between the evaluated variables, only lupus anticoagulant and the occurrence of at least three spontaneous abortions in the past predicted fetal loss, in contrast to anticardiolipin antibody isotype or level, systemic lupus erythematosus, or lupus-like disease and a history of thrombosis. In the patients with antiphospholipid antibodies, spontaneous abortion rates (12% for anticardiolipin antibody and 15% for lupus anticoagulant) were comparable with the normal population. However, in patients with lupus anticoagulant most fetal losses were after 12 weeks of gestation (four of seven losses in 20 pregnancies), whereas patients with a history of spontaneous abortions mainly had early abortions (10 of 14 losses in 33 pregnancies, Fig. 1). An increasing chance for a spontaneous abor-

Table II. Pregnancy outcome in relation to treatment in 59 pregnancies characterized by the presence of antiphospholipid antibodies

	Treatment including high-dose prednisone (n = 11)	*Treatment with low-dose aspirin (n = 16) or heparin (n = 3)*	*No treatment (n = 29)*

Treatment containing high-dose prednisone was significantly associated with low birth weight ($p = 0.002$), as analyzed with stepwise multiple regression.

*Of live infants.

tion after an unsuccessful past reproductive performance has been described earlier.[18] The cause of lupus anticoagulant–associated intrauterine fetal death is probably placental insufficiency, because signs of thrombosis or infarction were present in all placentas. This is in accordance with a recently published study of ours in which we demonstrated that intrauterine fetal death in patients with antiphospholipid antibodies is significantly associated with histopathologic features of thrombosis or infarction, compared with a control group of women with fetal loss without these antibodies.[19] We did not find a relation between anticardiolipin antibodies and fetal loss. This may be due to the antiphospholipid antibody–negative control group, which is not comparable with the normal population. We chose this control group because possible risk factors for adverse pregnancy outcome frequently found in women with antiphospholipid antibodies (systemic lupus erythematosus, prior fetal losses) were present in these patients. Use of this group made optimal discrimination between the impact of the various risk factors on pregnancy outcome possible. Therefore it is likely that the significant relations we found will be even more apparent when compared with the normal population. The composition of the control group may also be responsible for the fact that we did not find a significant relation between antiphospholipid antibodies and SGA newborns or pregnancy-induced hypertension or preeclampsia. Both conditions had a higher incidence in our control group than in a normal population. In the Netherlands SGA newborns are seen by definition in 10% of all pregnancies. Normal mean birth weight is 3445 gm.[16]

We found a 44% prevalence of antiphospholipid antibodies in our screening population, which included not only patients with bad obstetric histories but also patients with systemic lupus erythematosus and lupuslike disease referred to our center because of obstetric problems.

In live infants a low birth weight could be predicted independently by the presence of anticardiolipin antibodies, prior intrauterine fetal death, and treatment with high-dose prednisone. Birth before 37 weeks of gestation was seen significantly more often in pregnancies with antiphospholipid antibodies. This was in part artificial because of the significantly increased cesarean section rate associated with fetal distress. It further illustrates the poor fetal condition in pregnancies with antiphospholipid antibodies, leading to early obstetric intervention.

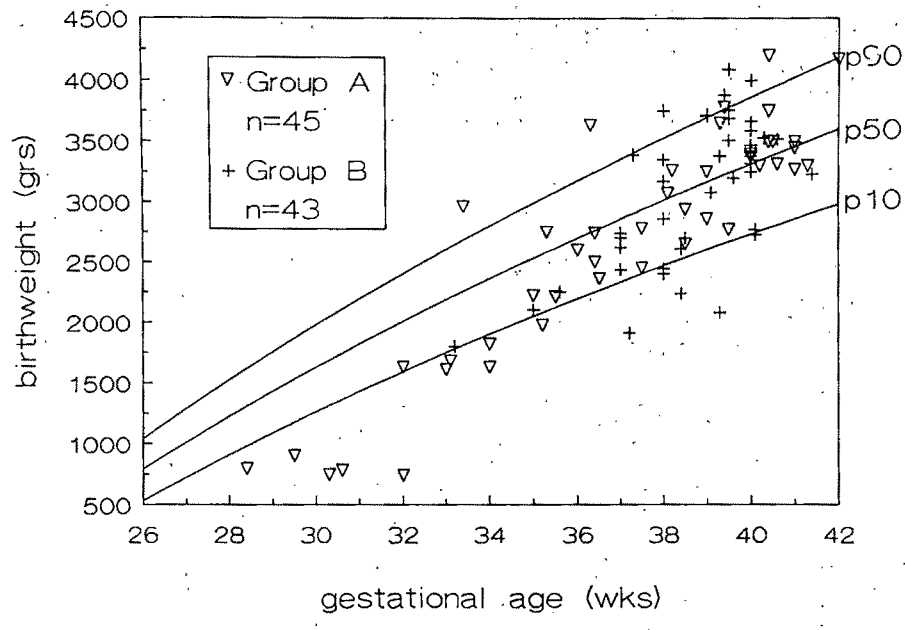

Fig. 2. Relationship of birth weight and gestational age of live infants, including 45 pregnancies with (group A) and 43 pregnancies without (group B) antiphospholipid antibodies compared with normal percentiles *(p10, p50, p90)*.

The initially intended randomization procedure failed due to patient reluctance to use high-dose prednisone. Besides, we demonstrated a significantly lower birth weight after treatment with high-dose prednisone during pregnancy. These are important observations in view of possible future randomized trials on this subject. We also could not demonstrate a superior outcome after prednisone therapy, which is in agreement with findings of Lockshin et al.,[9] who even found fetal loss in nine of 11 patients (84%) with high-positive anticardiolipin antibodies and prior fetal death. Our somewhat better results after prednisone treatment may be explained by the fact that our series included three patients without a prior fetal death and three patients with only low- or medium-positive anticardiolipin antibody levels in the absence of lupus anticoagulant. Considering these disappointing effects after steroid treatment, we believe that high-dose prednisone therapy is not the first choice in any forthcoming trial or in the management of individual patients. Unfortunately, our study does not allow firm conclusions on what treatment should be given instead, because of its limited size and nonrandomized nature.

Although it is often claimed that complete suppression of the antiphospholipid antibodies is mandatory for a favorable outcome,[7, 20] we could not confirm this concept. Therefore the use of high-dose prednisone for this purpose does not seem to be indicated. Instead, antithrombotic treatment with low-dose aspirin or heparin may be sufficient in preventing fetal loss, in spite of the prolonged presence of antiphospholipid antibodies. However, it was remarkable to notice that in the 29 patients with antiphospholipid antibodies who were not treated at all fetal loss occurred in 21%, compared with 22% in patients who received mild therapy with low-dose aspirin or heparin. The necessity of any treatment therefore remains to be proved. In conclusion, our prospective, controlled data indicate that lupus anticoagulant should be considered a risk factor for fetal loss and anticardiolipin antibodies for a low birth weight. Therefore pregnancies in women with antiphospholipid antibodies are high-risk pregnancies, demanding close fetal monitoring especially when a history of fetal loss is present. High-dose prednisone is not the first choice of treatment in these patients. Future randomized studies have to be done to establish whether close fetal surveillance is sufficient for a successful pregnancy or whether any antithrombotic drug treatment should be added for optimal outcome.

We thank Mrs. I. van der Tweel for statistical analysis and all Dutch specialists participating in the study.

TRI·LEVLEN® Levonorgestrel and ethinyl estradiol tablets—Triphasic regimen

TRI-LEVLEN® 28 TRI-LEVLEN® 21

BRIEF SUMMARY

Tri-Levlen®—6 brown tablets, each containing 0.050 mg of levonorgestrel (d(-)-13 beta-ethyl-17-alpha-ethinyl-17-beta-hydroxygon-4-en-3-one), a totally synthetic progestogen, and 0.030 mg of ethinyl estradiol (19-nor-17α-pregna-1,3,5(10)-trien-20-yne-3, 17-diol); 5 white tablets, each containing 0.075 mg levonorgestrel and 0.040 mg ethinyl estradiol; 10 light-yellow tablets, each containing 0.125 mg levonorgestrel and 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day triphasic regimen).

Indications and Usage

Oral contraceptives are indicated for the prevention of pregnancy in women who elect to use this product as a method of contraception.

Contraindications

Oral contraceptives should not be used in women with any of the following conditions: thrombophlebitis or thromboembolic disorders, a past history of deep-vein thrombophlebitis or thromboembolic disorders, cerebral-vascular or coronary-artery disease, known or suspected carcinoma of the breast, carcinoma of the endometrium or other known or suspected estrogen-dependant neoplasia, undiagnosed abnormal genital bleeding, cholestatic jaundice of pregnancy or jaundice with prior pill use, hepatic adenomas or carcinomas, known or suspected pregnancy.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral-contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia, gallbladder disease, and hypertension, although the risk of serious morbidity or mortality is very small in healthy women without underlying risk factors. The risk of morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, obesity and diabetes. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks. The information contained in this package insert is principally based on studies carried out in patients who used oral contraceptives with higher formulations of estrogens and progestogens than those in common use today. The effect of long-term use of the oral contraceptives with lower formulations of both estrogens and progestogens remains to be determined. Throughout this labeling, epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of disease, namely, a ratio of the incidence of a disease among oral-contraceptive users to that among nonusers. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide a measure of attributable risk, which is the difference in the incidence of disease between oral-contraceptive users and nonusers. The attributable risk does provide information about the actual occurrence of a disease in the population. For further information, the reader is referred to a text on epidemiological methods.

1. *Thromboembolic Disorders and Other Vascular Problems*

a. *Myocardial Infarction.* An increased risk of myocardial infarction has been attributed to oral-contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary-artery disease such as hypertension, hypercholesterolemia, morbid obesity, and diabetes. The relative risk of heart attack for current oral-contraceptive users has been estimated to be two to six. The risk is very low under the age of 30. Smoking in combination with oral-contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women in their mid-thirties or older with smoking accounting for the majority of excess cases. Mortality rates associated with circulatory disease have been shown to increase substantially in smokers over the age of 35 and non-smokers over the age of 40 among women who use oral contraceptives. Oral contraceptives may compound the effects of well-known risk factors, such as hypertension, diabetes, hyperlipidemias, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and cause glucose intolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see section 9 in "Warnings"). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors.

b. *Thromboembolism.* An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to nonusers to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep-vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. Cohort studies have shown the relative risk to be somewhat lower, about 3 for new cases and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease due to oral contraceptives is not related to length of use and disappears after pill use is stopped. A two-to four-fold increase in relative risk of postoperative thromboembolic complications has been reported with the use of oral contraceptives. The relative risk of venous thrombosis in women who have predisposing conditions is twice that of women without such medical conditions. If feasible, oral contraceptives should be discontinued at least four weeks prior to and for two weeks after elective surgery of a type associated with an increase in risk of thromboembolism and during and following prolonged immobilization. Since the immediate post partum period is also associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than four to six weeks after delivery in women who elect not to breast-feed, or a midtrimester pregnancy termination.

c. *Cerebrovascular diseases.* Oral contraceptives have been shown to increase both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes), although, in general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and nonusers, for both types of strokes, while smoking interacted to increase the risk for hemorrhagic strokes. In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for nonsmokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hypertension. The attributable risk is also greater in older women.

d. *Dose-related risk of vascular disease from oral contraceptives.* A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high-density lipoproteins (HDL) has been reported with many progestational agents. A decline in serum high-density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the nature and absolute amount of progestogen used in the contraceptive. The amount of both hormones should be considered in the choice of an oral contraceptive. Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral-contraceptive agents should be started on preparations containing less than 50 mcg of estrogen.

e. *Persistence of risk of vascular disease.* There are two studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40-49 years who had used oral contraceptives for five or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. However, both studies were performed with oral-contraceptive formulations containing 50 micrograms or higher of estrogens.

2. *Estimates of Mortality from Contraceptive Use.* One study gathered data from a variety of sources which have estimated the mortality rate associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral-contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is less than that associated with childbirth. The observation of a possible increase in risk of mortality with age for oral-contraceptive users is based on data gathered in the 1970's—but not reported until 1983. However, current clinical practice involves the use of lower estrogen dose formulations combined with careful restriction of oral-contraceptive use to women who do not have the various risk factors listed in this labeling. Because of these changes in practice and, also, because of some limited new data which suggest that the risk of cardiovascular disease with the use of oral contraceptives may now be less than previously observed, the Fertility and Maternal Health Drugs Advisory Committee was asked to review the topic in 1989. The Committee concluded that although cardiovascular-disease risks may be increased with oral-contraceptive use after age 40 in healthy nonsmoking women (even with the newer low-dose formulations), there are greater potential health risks associated with pregnancy in older women and with the alternative surgical and medical procedures which may be necessary if such women do not have access to effective and acceptable means of contraception. Therefore, the Committee recommended that the benefits of oral-contraceptive use by healthy nonsmoking women over 40 may outweigh the possible risks. Of course, older women, as all women who take oral contraceptives, should take the lowest possible dose formulation that is effective.

3. *Carcinoma of the Reproductive Organs.* Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. The overwhelming evidence in the literature suggests that use of oral contraceptives is not associated with an increase in the risk of developing breast cancer, regardless of the age and parity of first use or with most of the marketed brands and doses. The Cancer and Steroid Hormone (CASH) study also showed no latent effect on the risk of breast cancer for at least a decade following long-term use. A few studies have shown a slightly increased relative risk of developing breast cancer, although the methodology of these studies, which included differences in examination of users and nonusers and differences in age at start of use, has been questioned. Some studies suggest that oral-contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors. In spite of many studies of the relationship between oral-contraceptive use and breast and cervical cancers, a cause-and-effect relationship has not been established.

4. *Hepatic Neoplasia.* Benign hepatic adenomas are associated with oral-contraceptive use, although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases/100,000 for users, a risk that increases after four or more years of use. Rupture of rare, benign, hepatic adenomas may cause death through intra-abdominal hemorrhage. Studies from Britain have shown an increased risk of developing hepatocellular carcinoma in long-term (>8 years) oral-contraceptive users. However, these cancers are extremely rare in the U.S. and the attributable risk (the excess incidence) of liver cancers in oral-contraceptive users approaches less than one per million users.

5. *Ocular Lesions.* There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately.

6. *Oral-Contraceptive Use Before or During Early Pregnancy.* Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. Studies also do not suggest a teratogenic effect, particularly insofar as cardiac anomalies and limb-reduction defects are concerned, when taken inadvertently during early pregnancy. The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion. It is recommended that for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing oral-contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral-contraceptive use should be discontinued if pregnancy is confirmed.

7. *Gallbladder Disease.* Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral-contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral-contraceptive formulations containing lower hormonal doses of estrogens and progestogens.

8. *Carbohydrate and Lipid Metabolic Effects.* Oral contraceptives have been shown to cause glucose intolerance in a significant percentage of users. Oral contraceptives containing greater than 75 micrograms of estrogens cause hyperinsulinism, while lower doses of estrogen cause less glucose intolerance. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the nondiabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects, prediabetic and diabetic women should be carefully observed while taking oral contraceptives. A small proportion of women will have persistent hypertriglyceridemia while on the pill. As discussed earlier (see "Warnings" 1a. and 1d.), changes in serum triglycerides and lipoprotein levels have been reported in oral-contraceptive users.

9. *Elevated Blood Pressure.* An increase in blood pressure has been reported in women taking oral contraceptives and this increase is more likely in older oral-contraceptive users and with continued use. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing quantities of progestogens. Women with a history of hypertension or hypertension-related diseases, or renal disease should be encouraged to use another method of contraception. If women with hypertension elect to use oral contraceptives, they should be monitored closely, and if significant elevation of blood pressure occurs, oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives, and there is no difference in the occurrence of hypertension among ever-and never-users.

10. *Headache.* The onset or exacerbation of migraine or development of headache with a new pattern that is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause.

11. *Bleeding Irregularities.* Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first three months of use. The type and dose of progestogen may be important. Nonhormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding, as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out. Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was preexistent.

Precautions

1. PHYSICAL EXAMINATION AND FOLLOW UP. A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology, and relevant laboratory tests. In case of undiagnosed, persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care. 2. LIPID DISORDERS. Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult. (See "Warnings" 1d.) 3. LIVER FUNCTION. If jaundice develops in any woman receiving such drugs, the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function. 4. FLUID RETENTION. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention. 5. EMOTIONAL DISORDERS. Patients becoming significantly depressed while taking oral contraceptives should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug related. Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. 6. CONTACT LENSES. Contact-lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist. 7. DRUG INTERACTIONS. Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association, though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines. 8. INTERACTIONS WITH LABORATORY TESTS. Certain endocrine-and liver-function tests and blood components may be affected by oral contraceptives: a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. b. Increased thyroid-binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG, free T4 concentration is unaltered. c. Other binding proteins may be elevated in serum. d. Sex-binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids; however, free or biologically active levels remain unchanged. e. Triglycerides may be increased. f. Glucose tolerance may be decreased. g. Serum folate levels may be depressed by oral-contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives. 9. CARCINOGENESIS. See "Warnings" section. 10. PREGNANCY. Pregnancy Category X. See "Contraindications" and "Warnings" sections. 11. NURSING MOTHERS. Small amounts of oral-contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child.

Information for the Patient

See Patient Labeling.

Adverse Reactions

An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see "Warnings" section): thrombophlebitis, arterial thromboembolism, pulmonary embolism, myocardial infarction, cerebral hemorrhage, cerebral thrombosis, hypertension, gallbladder disease, hepatic adenomas or benign liver tumors.

There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: mesenteric thrombosis, retinal thrombosis.

The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug related: nausea; vomiting; gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; amenorrhea; temporary infertility after discontinuation of treatment; edema; melasma which may persist; breast changes: tenderness, enlargement, secretion; change in weight (increase or decrease); change in cervical erosion and secretion; diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening); intolerance to contact lenses.

The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted: congenital anomalies, premenstrual syndrome, cataracts, optic neuritis, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, cerebral-vascular disease with mitral valve prolapse, lupus-like syndromes, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, impaired renal function, hemolytic uremic syndrome, Budd-Chiari syndrome, acne, changes in libido, colitis, sickle-cell disease.

Overdosage

Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Noncontraceptive Health Benefits

The following noncontraceptive health benefits related to the use of oral contraceptives are supported by epidemiological studies which largely utilized oral-contraceptive formulations containing doses exceeding 0.035 mg of ethinyl estradiol or 0.05 mg of mestranol.

Effects on menses: increased menstrual cycle regularity, decreased blood loss and decreased incidence of iron-deficiency anemia, decreased incidence of dysmenorrhea.

Effects related to inhibition of ovulation: decreased incidence of functional ovarian cysts, decreased incidence of ectopic pregnancies.

Effects from long-term use: decreased incidence of fibroadenomas and fibrocystic disease of the breast, decreased incidence of acute pelvic inflammatory disease, decreased incidence of endometrial cancer, decreased incidence of ovarian cancer.

Dosage and Administration

To achieve maximum contraceptive effectiveness, TRI-LEVLEN® tablets (Levonorgestrel and Ethinyl Estradiol Tablets—Triphasic Regimen) must be taken exactly as directed and at intervals not exceeding 24 hours.

For full details on dosage and administration see prescribing information in package insert. 60627-0 5/90

Term birth after midtrimester hysterotomy and selective delivery of an acardiac twin

Norman A. Ginsberg, MD, Michael Applebaum, MD, Steven A. Rabin, MD, Melissa A. Caffarelli, MS, Monika Kuuspalu, RT, RDMS, Jay L. Daskal, MD, Yury Verlinsky, PhD, Charles M. Strom, MD, PhD, and John J. Barton, MD

Chicago, Illinois

OBJECTIVE: Our aim was to determine whether hysterotomy and selective removal of an acardiac twin could improve the outcome of the "pump" twin.

STUDY DESIGN: A literature and case review of the outcome of the acardiac twin malformation was performed. When an acardiac malformation was diagnosed at 19 weeks' gestation the patient was monitored with weekly ultrasonographic examinations. At 23 weeks' gestation, no blood flow could be demonstrated to the acardiac twin and it was thought that the continued presence of the acardiac twin posed a risk to the "pump" twin. A midtrimester hysterotomy was performed and the acardiac twin was delivered.

RESULTS: After the midtrimester hysterotomy, the pregnancy progressed to term and a healthy female infant was delivered by elective cesarean section at 37 weeks' gestation.

CONCLUSION: Midtrimester hysterotomy may be a useful intervention in cases of twinning when one fetus is a threat to the health of the other. (AM J OBSTET GYNECOL 1992;167:33-7.)

Key words: Acardiac twin, fetal surgery, midtrimester hysterotomy, term delivery, acardiac in triplets

The acardiac twin malformation has been reported to occur in 1 in 34,600 pregnancies and is unique to multiple gestations containing monozygotic twin pairs.[1] The epidemiologic features of the acardiac deformity have been studied by James,[2] and his review of 340 cases revealed that the complication occurs considerably more frequently among monoamniotic than diamniotic monochorionic twins. Acardiac twins occur in 1% of monozygotic twins but three times more frequently in monozygotic twin pairs in higher-order multiple births. A slight female predominance has also been noted.[1-5]

Four morphologic types have been described by Napolitani and Schreiber[3]: (1) The condition is designated hemiacardius when the fetus has some rudimentary cranial structures. (2) Holoacardius acephalus is the most commonly described. These fetuses lack cranial and thoracic organs. Pelvic bones and lower extremities are well developed and upper extremities may or may not develop. (3) Holoacardius acormus is the rarest form and consists of a head without a body. (4) Holoacardius amorphus is the least-developed type with no recognizable human form.

The acardiac malformations are uniformly fatal in the affected twin, and mortality in the co-twin has been reported by Moore et al.[4] to be as high as 55%. Moore et al. tabulated the perinatal outcomes of 49 pregnancies complicated by the presence of acardiac twinning. The principal problems were congestive heart failure of the "pump" twin (nonacardiac twin), polyhydramnios, and preterm labor. In that series therapeutic amniocentesis was the only invasive form of management attempted. Their findings of 50% mortality provide a standard against which newer management schemes can be compared. Furthermore, only 25% of their pregnancies progressed to term.[4]

Antenatal diagnosis of the condition by ultrasonography was first reported in 1978, allowing the first opportunity to consider antepartum management of this condition.[5]

The described therapeutic management in cases of one acardiac twin diagnosed antenatally includes the following: (1) continuation of the pregnancy in the interest of the normal twin, (2) termination of the entire pregnancy in spite of the presence of one normal fetus, (3) selective delivery of the abnormal fetus,[6] (4) serial amniocentesis for treatment of polyhydramnios in the "pump twin,[7] (5) maternal administration of digoxin in an effort to treat cardiac failure in the "pump" twin,[8] and (6) placement of a thrombogenic coil to obstruct blood flow to the acardiac fetus. The use of the thrombogenic coil has been reported by Porreco et al.[9] in a case of occlusion of the umbilical artery of the acardiac

twin. The "pump" twin was delivered at 39 weeks and was healthy. Personal communication with a physician from Tokyo, Japan, on the use of the thrombogenic coil has shown somewhat disappointing results. He has treated four patients with this method and found it to be effective in only 50% of patients. In addition, he and others (personal communications) have found the obstruction created by the coil to be transient in some cases.

Umbilical cord clamping via an intrauterine laparoscopic procedure has been proposed and was planned for a patient who was delivered prematurely before the procedure could be performed.[8]

Successful selective delivery of the acardiac twin via hysterotomy and continuation of the pregnancy with the viable fetus has been reported by Robie et al.[6] That pregnancy was delivered prematurely at 32 weeks. Our report describes hysterotomy and selective delivery of an acardiac twin, after which the pregnancy progressed to term before elective delivery was performed. The only other term delivery after a midtrimester hysterotomy was performed by Beck et al.[10] when one twin was removed because it was affected with Down syndrome.

First, we describe a case of a triplet pregnancy with an acardiac fetus, managed conservatively, in which the pump triplet died neonatally in spite of a near-term delivery.

Case reports

Case 1. A 20-year-old primigravid woman was referred to our center at 28 weeks of gestation. The fundal height at that time measured 43 cm, and ultrasonographic evaluation revealed a triplet gestation. Triplet A was in a cephalic presentation and was shown to be appropriate for gestational age at 28 weeks. Polyhydramnios was present. Triplet B was concordant with A and in a cephalic presentation. Amniotic fluid volume was normal. Triplet C was in a transverse lie in the fundus. The femur length of triplet C corresponded to 25 weeks' gestation, and no thorax, upper extremities, or head was present. This fetus shared a circulation with triplet A. Preterm labor began at 28 weeks, and successful tocolysis was achieved with magnesium sulfate. Later a switch was made to an oral β-adrenergic receptor agonist. At 34 weeks the patient presented with spontaneous rupture of membranes and in active labor; delivery was accomplished. Triplet A, the pump triplet, weighed 1630 gm and had Apgar scores of 8 and 9 at 1 and 5 minutes, respectively. This triplet did well for the first 24 hours and then went into intractable heart failure and died. Autopsy of that neonate failed to reveal any structural cardiac abnormality other than massive cardiac dilatation as a secondary effect of heart failure. No other developmental anomalies were present. Triplet B had an uneventful neonatal course.

Case 2. A 30-year woman, gravida 4, para 3-0-0-3, presented for her first prenatal visit at 14 weeks' gestation. The patient became extremely orthopneic and dyspneic at 19 weeks and was uncomfortable presumably because of polyhydramnios. Ultrasonographic examination revealed a monochorionic, diamniotic twin gestation with an acardiac fetus approximately two thirds the size of the pump twin. The pregnancy was diamniotic, and polyhydramnios was seen in the sac of the pump twin only. The umbilical cord of the acardiac twin could be seen originating from a portion of the pump twin's cord. Doppler flow studies demonstrated reversed flow in the acardiac twin's umbilical cord. Alternatives of management presented to the patient included (1) termination of the entire pregnancy, (2) expectant management, and (3) selective removal of the malformed fetus. The presence of an anterior placenta that covered the entire anterior surface of the uterus prevented the possibility of any percutaneous approach. Although the thrombogenic coil has been mentioned here, this case occurred before the report of the Porreco et al. appeared in the Lancet, and therefore that option was not offered to the patient.

Both the institutional ethics committee and the institutional review board were convened, and they determined that if the pump twin became at significant risk selective removal of the acardiac twin would be appropriate. Amniocentesis was performed at the nineteenth week of gestation for chromosomal evaluation and relief of the symptomatic polyhydramnios. Fluid rapidly reaccumulated after therapeutic amniocentesis at 19 weeks. It was our opinion that further therapeutic amniocentesis was not likely to be effective, in contrast to cases of twins with the twin-twin transfusion syndrome, because the hemodynamic situations are vastly different. No further invasive procedures were attempted to preclude iatrogenic premature rupture of membranes.

Karyotypic evaluation revealed that both twins had identical karyotypes with inversion of chromosome 10:46,XX,inv(10)(p12q25). Further studies revealed that the mother and her two tested children carry the same inversion and were phenotypically normal.

Weekly ultrasonographic examinations showed that, inspite of therapeutic amniocentesis, the polyhydramnios progressively worsened. Evaluation at 23 weeks' gestation demonstrated skin edema and total cessation of movements, as well as diminished blood flow in the cord of the acardiac twin. Two days later skin edema drastically worsened in the acardiac fetus, and flow through the umbilical cord could no longer be consistently demonstrated. There was concern regarding a dead twin in a monochorionic twin pregnancy. The institutional ethics committee and institutional review board were convened, and they determined that, because of the risk to the pump twin, selective delivery of the acardiac fetus would be appropriate.

The team was assembled in preparation for a hysterotomy the following morning. Pretreatment with indomethacin the night before was initiated. Enflurane was used to provide deep general anesthesia and furnish adequate uterine relaxation. Through a large mid-

line incision, the uterus was exteriorized to allow an approach to the posterior surface of the uterus. Sterile intraoperative ultrasonography was used both to determine the location for the uterine incision and to monitor the pump twin during the procedure. After the uterus was entered, the amniotic membrane was sutured to the incision line, and the acardiac fetus was then extracted. The umbilical cord of the abnormal twin was identified and tied off with Merseilene tape. The then-empty sac of the acardiac twin was instilled with warmed saline solution mixed with nafcillin. The uterus was then closed in layers after the application of fibrin glue to provide a watertight seal and control of hemostasis. Postmortem evaluation of the acardiac fetus revealed substantial edema in a female hemiacardius. The umbilical cord demonstrated some thrombosis.

Postoperative care included the continuation of indomethacin and magnesium sulfate until conversion to an oral β-adrenergic receptor agonist could be accomplished. Uterine activity was minimal during the patient's entire postoperative course. The patient was discharged on the seventh postoperative day on a regimen of terbutaline and home uterine monitoring.

The patient was examined weekly, and the polyhydramnios resolved along with the orthopnea. The remaining fetus continued to develop normally, and the remainder of the patient's prenatal course was completely uneventful. At 38 weeks gestation, after an amniocentesis was performed to assure pulmonary maturity, the fetus was electively delivered by cesarean section. Examination of the posterior surface of the uterus, at the site of the prior hysterotomy, showed a dense adhesion to a portion of small bowel. The myometrium was otherwise well healed and normal in appearance. A female infant weighing 3040 gm was delivered. The Apgar scores were 9 and 9 at 1 and 5 minutes, respectively. The placenta was expressed out without difficulty, and the vascular anastomosis with the acardiac twin can be seen in Fig. 1. Physical examination of the infant was unremarkable except for a very small membranous ventricular-septal defect that has closed spontaneously. The mother had an uneventful postoperative recovery. The child is now 8 months old and is developing normally without any medical problems.

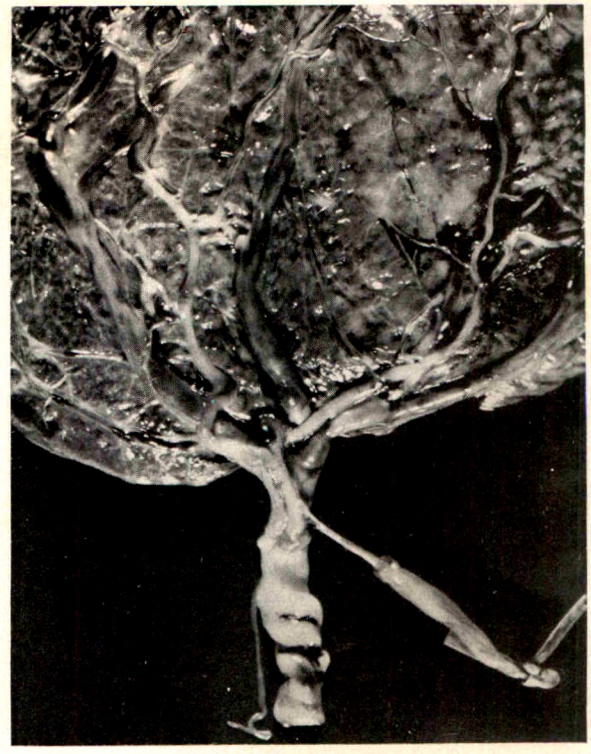

Fig. 1. Term placenta with cord insertion of acardiac twin.

Comment

This case represents a term delivery after hysterotomy as part of fetal therapy. The contemplation of open fetal surgery poses a dilemma from the physician's perspective with respect to the best way to balance the needs of the fetus and their implications for the mother. The use of open fetal surgery automatically commits the mother to two major operations, a hysterotomy followed by a cesarean section, with all of their potential associated morbidity. For these reasons case selection is especially important.

The disease entity in which surgery is selected should have a high likelihood of resulting in a functionally normal child and should have an otherwise dismal prognosis if treated by conventional noninvasive measures. Toward this end, the fetus should be completely evaluated by both a chromosome analysis, because there are reported cases of chromosomal anomalies in the pump twin,[11] and a detailed ultrasonographic study. Similarly, the mother must be prepared both physically and emotionally to cope with the restrictive postoperative prenatal care program that is essential to a successful outcome.

The selection of acardiac twins as a model for open fetal surgery is appropriate for several reasons. Acardiac twins, although a rare occurrence, have a large body of literature written about their natural outcome.[1-4] Removal of the acardiac twin does not create an ethical dilemma because it cannot survive outside the uterus. The pump twin is generally normal and can be expected to function normally if it can be delivered as a mature fetus in good condition. Furthermore, parameters have been developed to predict the likely consequences of nonintervention[4] and provide a data base from which conclusions on outcome can be drawn. In the series of Moore et al.[4] no invasive therapeutic modalities were used other than amniocentesis to relieve polyhydramnios, which was performed in four of 49 cases. Those authors described the relationship between the weight of the acardiac twin and that of the

pump twin to predict the outcome. When the weight of the acardiac twin exceeded 70% of that of the pump twin, congestive heart failure developed in 100% of the pump twins. When the acardiac/pump twin ratio was ≥50%, 64% of the pump twins died. Hydramnios was strongly associated with preterm delivery and congestive heart failure. Eighty-two percent of patients with hydramnios experienced preterm labor, and congestive heart failure developed in 78%. When the acardiac/pump twin ratio was ≤25%, the likelihood of adverse outcome was very small.

Deciding on the appropriate time to intervene in this case was based on several assumptions. It was our opinion that the pump twin was likely to fare better if surgery was performed before the fetus became hydropic. The experience of Platt et al.[8] suggests that surgery should be performed before the onset of premature labor, because once premature labor begins, it may not be possible to stop it. Anderson et al.[12] and others have reported that death of one monozygotic twin may lead to disruptive structural defects in the central nervous system, gastrointestinal tract, renal system, and terminal limbs, as well as death, in its co-twin. The incidence of these complications has been reported as 46%.[13]

A longitudinal midline skin incision was used, rather than a transverse incision, which is generally used by Harrison (and his group[14] in San Francisco) to allow for easier exposure to the posterior surface of the uterus. The skin incision should not be allowed to compromise the procedure for cosmetic reasons.

Care was taken to plan the uterine incision as far away from the placental edge as possible and yet make it large enough to remove the acardiac twin without entering the sac of the pump twin.

Monitoring the pump twin during the surgery provides a unique problem since it is not readily accessible. This was done by continuous ultrasonographic visualization and with intermittent Doppler readings to measure the systolic/diastolic ratio. Monitoring of the pump twin was done because there was concern that exteriorization of the uterus might compromise uteroplacental blood flow or potentially compress the fetus against the umbilical cord.

Reversed umbilical artery blood flow to the acardiac twin has been described by Pretorius et al.,[15] Kirkinen et al.,[16] and Benson et al.[17] Different investigators have arrived at different conclusions in their study of umbilical artery waveforms demonstrated in the twin arterial perfusion sequence. Farmakides et al.[18] and Sherer et al.[19] obtained discordant umbilical waveforms, while Giles et al.[20] determined that twin transfusion syndrome with discordant growth is associated with the presence of concordant waveforms. Cyclic alterations of umbilical artery waveforms in a monochorionic gestation were described by Erskine et al.[21] Pretorius et al.[22] noted no consistent patterns of the umbilical waveforms in eight cases of twin arterial perfusion sequence. Similarly, Neilson et al.[23] were unable to discern any consistent pattern of umbilical artery waveforms resulting from vascular anastomoses in monochorionic gestations. In our case both reversed flow and discordant umbilical artery waveform patterns were present.

The chorioamniotic membranes were handled in a different way than described by Robie et al.[6] The membranes were sutured to the hysterotomy incision line rather than being stapled. We chose to suture them to avoid being confined by the size of the staples. Chromic suture material rather than polyglycolic was used.

Great care was taken to assure that no instruments placed on the uterine incision to control hemostasis ever incorporated any portion of the membranes.

Fibrin glue was used to seal the chorioamniotic membranes against leakage. This substance was first used for this indication by Genz[24] in 1979, when he treated premature rupture of membranes at 16 and 23 weeks. Electron microscopy suggested that this substance promotes the regeneration of amniotic membrane at the site of the defect. Adamyan et al.[25] in their review of fibrin glue in obstetrics and gynecology have shown it to promote reparative regeneration and to decrease adhesion formation. We were impressed by the excellent hemostasis that could be achieved at the hysterotomy site.

One can only speculate what factors allowed this case to go to term, whereas most other cases of open fetal surgery have ended in premature labor. Several factors may be of significance, such as refilling the sac of the acardiac twin to let the uterus gradually decrease in size rather than abruptly. An additional advantage to refilling the acardiac twin's sac was to provide a liquid buffer at the hysterotomy site against the movements of the pump twin. Timing the surgery to occur before the pump twin was significantly compromised likely improved its ability to tolerate the stress of surgery. Having an established team specifically dedicated to performing this procedure facilitated a smooth flow from start to finish. Finally, having a highly motivated and compliant patient certainly contributed to our success.

Aggressive surgical management can result in successful intervention in pregnancies where ultrasonographic monitoring indicates that a fetus is in imminent danger of significant morbidity or mortality as elucidated by Moore et al.[4] When the acardiac/pump twin ratio is ≤25%, conservative management generally will result in a term delivery without development of hydrops. The first case presented illustrates that near-term delivery is not the only criterion for a good outcome. The fetus must also be hemodynamically able to

withstand the change in circulation to an extrauterine environment. In those circumstances where surgery can correct the anatomic defect that cannot wait for delivery, patients should be referred to centers with experience in these techniques. Centralized referral of these rare cases is likely to improve the outcome and facilitate meaningful data collection on the safety of this kind of alternative.

Idiopathic myelofibrosis in pregnancy: A case report and review of the literature

Udele B. Taylor MD, Arlene D. Bardeguez, MD, Nidia Iglesias, MD, and Pedro Gascon, MD, PhD

Newark, New Jersey

Idiopathic myelofibrosis is a rare myeloproliferative disorder characterized by excessive accumulation of connective tissue in the bone marrow n association with anemia, splenomegaly, and extramedullary hematopoiesis. The cause of this disease is unknown, and the prognosis is generally poor. To our knowledge, this is the first case report of a patient with idiopathic myelofibrosis who carried a term pregnancy. In spite of the increased perinatal risks, a favorable outcome was possible with close antepartum surveillance. (AM J OBSTET GYNECOL 1992;167:38-9.)

Key words: Idiopathic myelofibrosis

Myelofibrosis is a myeloproliferative disorder characterized by an abnormal accumulation of connective tissue in the bone marrow, extramedullary hematopoiesis, and leukoerythroblastic anemia. The cause of this disease is unknown,[1] and in the absence of an underlying malignant process the term idiopathic myelofibrosis is used.[2]

The signs and symptoms are often vague; therefore definitive diagnosis requires a bone marrow biopsy. The prognosis for these patients is extremely poor, with a 5-year survival of 9 to 30 months, often complicated by infections, cardiovascular diseases, and thrombohemorrhagic events.[2] The physiologic alterations of pregnancy may further complicate the clinical course of patients with idiopathic myelofibrosis. These patients are therefore at increased risk for poor perinatal outcome.

To our knowledge, our report describes the first patient with primary myelofibrosis who was delivered of a term infant and includes our recommendations for a multidisciplinary approach and close antepartum surveillance of these pregnancies.

Case report

A 23-year-old primiparous woman was referred to University Hospital for prenatal care at 15 weeks' gestation. Her medical history was significant for idiopathic myelofibrosis with diffuse osteosclerosis diagnosed 3 years before this pregnancy. Her history was also significant for a leukoagglutinin reaction to a packed red blood cell transfusion in 1988. The family history was significant for myelofibrosis in her brother. Management by hematologists had been supportive before this pregnancy, with the use of hematinics and analgesics for joint pain.

On physical examination she was noted to have mild splenomegaly. Ultrasonography revealed a single appropriate-for-gestational-age fetus. Laboratory workup showed white blood cell count 5600/mm³, hemoglobin 6.4 gm/dl, hematocrit 21.8%, and platelet count 88,000 μm/L. Anemia workup revealed a normochromic, normocytic pattern. The reticulocyte count was in the normal range, but an elevated serum erythropoietin level of 2140 mU/ml (normal <19 mU/ml) was observed.

The patient's constitutional symptoms (joint pain) did not worsen during pregnancy. The lowest hematologic parameters were at 28 weeks' gestation with hemoglobin 6.3 gm/dl, hematocrit 19.2%, and platelet count 88,000 μm/L. Fetal growth was adequate as documented by serial ultrasonography, and all studies of fetal well-being were normal. After fetal lung maturity was documented, elective induction of labor was performed at 36 weeks, followed by spontaneous vaginal delivery of a 3100 gm female infant, with Apgar scores of 8 and 9 at 1 and 5 minutes, respectively. The neonate's nursery course was uncomplicated. The patient is currently undergoing management of her case by her hematologist 1 year after delivery without worsening disease.

Comment

Myelofibrosis was first described in 1879 by Hueck. Theories proposed to explain the cause of idiopathic myelofibrosis suggest that the disease occurs as a result of the bone marrow's reaction to neoplastic invasion, viruses, toxins, ionizing radiation, or chemotherapeutic agents.[1, 2] Although there is no known pattern of in-

heritance for the disease, karyotypic abnormalities among affected individuals suggest a genetic basis.[1] In our case, the patient's brother was diagnosed with the same disease 2 years earlier.

Although many patients with idiopathic myelofibrosis may be asymptomatic at the time of diagnosis, some are seen with fatigue, weight loss, dyspnea, and fever.[2] The most common medical complications noted in idiopathic myelofibrosis patients are infections (63%), cardiovascular disease (59%), and thrombohemorrhagic complications (49%).[2]

Therapy for asymptomatic individuals is generally supportive. Bone marrow transplantation, splenectomy, androgens, and chemotherapy have been used to treat some individuals with limited success.[1] Recently, α-interferon and erythropoietin have been recommended by some investigators. The elevated level of erythropoietin in our patient eliminated its potential use as an alternative treatment. The prophylactic use of blood transfusions has been recommended for some patients with chronic anemia; however, this does not generally improve perinatal outcome.

In summary, patients with idiopathic myelofibrosis should be carefully monitored during pregnancy for maternal and fetal well-being. Our experience showed that a favorable outcome is possible with close antepartum surveillance. However, the long-term prognosis of an intercurrent pregnancy on this disease is uncertain.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1992 issues from the Publisher, at a cost of $68.00 for domestic, $95.76 for Canada, and $91.00 for international for Vol. 166 (January-June) and Vol. 167 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351, or (314) 453-4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Oral contraceptive use and the incidence of cervical intraepithelial neoplasia

Inger T. Gram, MD,[a] Maurizio Macaluso, MD, DrPH,[c] and Helge Stalsberg, MD[b]
Tromsö, Norway, and Birmingham, Alabama

OBJECTIVE: Our objective was to examine the relationship between oral contraceptive use and the incidence of cervical intraepithelial neoplasia.
STUDY DESIGN: In a prospective follow-up study of 6622 women participating in the Second Tromsö Study conducted in 1979 and 1980 in Tromsö, Norway, women aged 20 to 49 years answered a questionnaire regarding their smoking history, dietary habits, alcohol consumption, and oral contraceptive use. They were then followed for 10 years with data from the Pathology Registry of the University Hospital.
RESULTS: The age-adjusted incidence rate of cervical intraepithelial neoplasia was 897 per 100,000 person years among noncurrent and 1295 per 100,000 person years among current oral contraceptive users as of 1979. After adjusting for age, marital status, smoking, and frequency of alcohol intoxication the relative rate for current users was 1.5 (95% confidence interval 1.1 to 2.1), and the relative rate for past users was 1.4 (95% confidence interval 1.0 to 1.8), as compared with those who had never used oral contraceptives before 1979.
CONCLUSION: These findings support the hypothesis that the occurrence of cervical intraepithelial neoplasia is increased by oral contraceptive use. (Am J Obstet Gynecol 1992;167:40-4.)

Key words: Oral contraceptives, cervical dysplasia, follow-up studies, Norway, cervical neoplasms

In two extensive reviews it was concluded that a weak positive association seems to be emerging between oral contraceptive use and the risk of cervical neoplasia but that this association may be due to bias and confounding.[1,2] The relationship remains controversial because recent epidemiologic studies continue to yield conflicting results.[3-7] It has been proposed that the findings of positive studies reflect enhanced detection of cervical intraepithelial neoplasia among oral contraceptive users rather than a causal association.[8]

We observed that among women who participated in the Second Tromsö Study and who were current oral contraceptive users as of 1979, grade 3 cervical intraepithelial neoplasia incidence during the following 10 years was 1.4 times higher than among nonusers.[9] Although this increased incidence among oral contraceptive users was not explained by confounding factors such as cigarette smoking or the number of cytologic examinations (Papanicolaou smears), it lacked statistical significance. In this report we expand the previous analysis by evaluating the relationship between oral contraceptive use and all cervical intraepithelial neoplasia grades and by adding information from the Third Tromsö Study.

Material and methods

Between 1979 and 1980 all women (n = 9906) aged 20 through 49 years and all men (n = 11,423) aged 20 through 54 years living in the municipality of Tromsö were invited to participate in the Second Tromsö Study. Complete details of the study methods are given elsewhere.[10] The participants filled out one questionnaire at the screening facility and another at home. The first questionnaire concerned disease history and aspects of living habits, including cigarette smoking and oral contraceptive use. The second questionnaire elicited information on dietary habits, alcohol and coffee consumption, previous diseases, and social and psychologic conditions. The participants were instructed to return this questionnaire by mail. The Third Tromsö Study was conducted in 1986 and 1987. At this survey the questionnaires were modified to add information on use and duration of oral contraceptives and intrauterine contraceptive devices, age at first marriage or cohabitation, and age at first pregnancy.[11]

Women participating in the Second Tromsö Study (n = 8134) with no history of the disease were followed for the development of cervical intraepithelial neoplasia or cervical cancer. The follow-up was made possible by linkage of their national personal identification

numbers with the computerized information in the Pathology Registry of the University Hospital in Tromsö. This registry provides complete records of all cytologic and histologic diagnoses made in the county where Tromsö is located. Altogether 7838 (96%) women from the Second Tromsö Study had a cervical specimen recorded in the registry during 1980 through 1989.

Criteria for inclusion in the analytic cohort were (1) no diagnosis of cervical intraepithelial neoplasia or cancer of the cervix before Jan. 1, 1980, and (2) at least one normal cervical specimen within 3 years before enrollment in the Second Tromsö Study or after enrollment. Excluded from follow-up were 528 women who had a diagnosis of cervical intraepithelial neoplasia or invasive cancer of the cervix before enrollment or as their first cervical specimen recorded in the registry. Follow-up began on Dec. 31, 1979, for 5415 women who had a normal specimen during the previous 3 years and on the date of the first normal specimen recorded for the remaining 1895 women. However, 688 women had no subsequent specimens and contributed no information to the follow-up study. Thus the analysis is restricted to 6622 women (81% of all participants in the Second Tromsö Study). Follow-up ended on the date of diagnosis of cervical intraepithelial neoplasia, autopsy or hysterectomy, or their last cervical specimen, whichever was earliest.

Incident cervical intraepithelial neoplasia cases were classified according to the first diagnosis. Thus, if during the study period a woman had a first diagnosis of grade 1 disease that later progressed to grade 3, she was counted only once as a grade 1 case.

Person years of follow-up were assigned to categories of potential determinants of risk for cervical intraepithelial neoplasia. Incidence rates were computed by dividing the number of cases by the number of person years in that category. Age-adjusted rates were calculated by the direct method, using the age distribution of person-years in the entire analytic cohort as the standard.[12] Data analysis included an evaluation of incidence rates by age, marital status, education, age at first pregnancy, age at first marriage or cohabitation, frequency of fruit and vegetable consumption, frequency of fish consumption, frequency of drunkenness, cigarette smoking, number of specimens, and time between specimens. Cases and person years were classified into current and noncurrent oral contraceptive users as of 1979 on the basis of information obtained from the Second Tromsö Study. More detailed information on the history of oral contraceptive use was available for 4912 (74%) who also participated in the Third Tromsö Study. Data from the third study were used to ascertain whether women who were nonusers at the time of enrollment into the second study had ever used oral contraceptives before that date (past users). Thus cases and person years were reclassified into never users, past users, and current users. Women from the Second Tromsö Study who were noncurrent users at enrollment and who did not participate in the third study were classified as "other noncurrent users." It is likely that this group is a mixture of never and past users.

The relative rate was used to compare category-specific incidence rates. Relative rates were also estimated with the Cox proportional hazards regression model to adjust simultaneously for the effects of several potential confounders.[13] The follow-up experience of subjects was analyzed by blocking on the number of specimens (one or two, three or four, five or six, seven or more) that they had accumulated during the follow-up period. This blocking was done because the likelihood that a diagnosis of cervical intraepithelial neoplasia is made during the observation period increases with more frequent screening. However, the results did not change materially whether the analysis was performed without the blocking factor or by including the number of specimens as covariates.

Poisson regression models were also used to obtain relative rate estimates adjusted for time between screens (and the confounding variables included in the proportional hazards model) and to evaluate interaction among potential risk factors. The significance of a trend in the incidence of cervical intraepithelial neoplasia with increasing levels of a factor was evaluated by assigning equally spaced ordinal scores to categories of the factor and including the score as a continuous variable in a Poisson regression model.[14] Multiplicative terms between oral contraceptive use and possible confounders were included in the model to evaluate interaction.

Results were considered statistically significant if the p value was ≤ 0.05. The 95% confidence intervals are reported throughout the paper. The proportional hazards regression analyses were performed with the PHGLM procedure of the SAS statistical package.[15] The Poisson regression analyses were performed with the EGRET statistical package.[16]

Results

During the 43,316 person years of observation, 401 incident cases (354 women with grade 1 or 2 cervical intraepithelial neoplasia as their first abnormal diagnosis, 44 with grade 3 cervical intraepithelial neoplasia, and three with cervical cancer) were identified. These women are included in all analyses. We note that inclusion of only the 354 women with grade 1 or 2 cervical intraepithelial neoplasia in the analysis did not change the results materially.

Seventy percent of the women were married, their median years of schooling were 11 (7 to 23), and at the beginning of the follow-up their median age was 31 (20

Monthly or more	1.9	1.3-2.7

*Based on 348 cases from Cox proportional hazards model with age group, marital status, smoking status, frequency of intoxication by alcohol, and oral contraceptive use blocking for number of specimens.

to 64) years. Only 9% of the women were current oral contraceptive users in 1979 and 1980.

For never, past, and current oral contraceptive users the mean follow-up time was 7 years and the average number of specimens obtained was five. The women who were noncurrent users in 1979 with missing information on ever use (women who did not participate in the Third Tromsö Study in 1986 and 1987) had an average number of four specimens obtained during the mean follow-up period of 5 years.

Prevalence of oral contraceptive use was higher among women of young age, among unmarried women, among cigarette smokers, and among women reporting frequent intoxication by alcohol (Table I). The relative rate estimates of cervical intraepithelial neoplasia from the proportional hazards regression models show that these women also have a significantly increased risk for cervical intraepithelial neoplasia (Table II). Thus each of these factors was considered a potential confounder of the oral contraceptive–cervical intraepithelial neoplasia association, and adjustment was made for each in a multivariate proportional hazards model. No meaningful associations were found between cervical intraepithelial neoplasia and years of schooling, fruit and vegetable consumption, or fish consumption.

The age-adjusted incidence rate of cervical intraepithelial neoplasia was 897 per 100,000 person years among noncurrent and 1295 per 100,000 person years among current oral contraceptive users as of 1979 ($p = 0.05$). A multivariate proportional hazards regression model on 348 cases with complete information on potential confounders (age in 5-year groups, marital status [married, divorced-widowed, single], smoking status [never, past, current], frequency of intoxication by alcohol [never, less than monthly, monthly or more]) yielded increased relative rate estimates of cervical intraepithelial neoplasia among noncurrent, past, and current oral contraceptive users as of 1979 as compared with never users. Women starting at an earlier age were at an increased risk as compared with those starting later. An ordinal trend test across the four categories for age started oral contraceptive use yielded a p value of 0.05 (Table III).

Women who married or cohabited for the first time at a young age had an increased risk for cervical intraepithelial neoplasia. This association was, however, explained by marital status. Neither did ever using intrauterine contraceptive devices or age started intrauterine contraceptive device use explain the oral contraceptive–cervical intraepithelial neoplasia association reported.

None of the two-way interaction terms between oral contraceptive use and age, marital status, smoking, drunkenness, time between screens, and number of screens was statistically significant or meaningfully affected the relative rates presented above.

Comment

The results of this follow-up study suggest that both current and past oral contraceptive users experience a

higher incidence of cervical intraepithelial neoplasia than do those who never used oral contraceptives. This finding is similar to those of four[17-20] of five previous follow-up studies[17-21] that evaluated the oral contraceptive–cervical intraepithelial neoplasia hypothesis.

The present study also suggests a relationship between age at start of oral contraceptive use and cervical intraepithelial neoplasia incidence. This association may in fact reflect an increasing trend of cervical intraepithelial neoplasia incidence with duration of oral contraceptive use. Three of the previously mentioned follow-up studies found a trend of increasing incidence with duration of oral contraceptive use.[17-19]

A major strength of this study is that it originates from a population-based survey with a high attendance rate. Thus the women constituting the cohort should be fairly representative of all women of similar age in the region. Strengths related to the prospective follow-up design are that women were known to be free of cervical intraepithelial neoplasia at enrollment and information on potential risk factors was collected before diagnosis. The oral contraceptive use among subjects was ascertained before outcome and hence is not subject to differential anamnestic bias, which may affect the results of case-control studies. Another strength of this study is the ability to control for confounding variables such as marital status, smoking status, and freqency of drunkenness. Because the number of Papanicolaou smears and the time between smears were also controlled for, it is unlikely that our results are explained by detection bias.

On the other hand, misclassification may result from higher rates of false-positive tests (from higher incidence of vaginal infections and cervical erosions) in oral contraceptive users. This misclassification would result in a spuriously high incidence of low-grade lesions (grade 1). We found that the incidence of grade 3 also was increased among oral contraceptive users.[9] Also, the excess cervical intraepithelial neoplasia incidence should be experienced only by current users, whereas incidence is increased among past oral contraceptive users.

The most important limitation of this study is the lack of information on sexual behavior. As in the other follow-up studies, it was not feasible to collect such data. However, it is likely that this source of confounding was partially controlled for in the analysis by adjusting for marital status and frequency of drunkenness. Information on sexual behavior is easier to collect in case-control studies. Two recent case-control studies found a positive association between oral contraceptive use and cervical intraepithelial neoplasia after controlling for number of sexual partners.[6-7]

In conclusion, the current study supports the hypothesis that the occurrence of cervical intraepithelial neoplasia is increased by oral contraceptive use.

Calcium homeostasis in pregnant women receiving long-term magnesium sulfate therapy for preterm labor

Leon G. Smith, Jr., MD,[a] Pamela A. Burns, RN,[b] and Richard J. Schanler, MD[b, c]
Houston, Texas

OBJECTIVES: The hypothesis of this study is that calcium homeostasis and bone mineralization are altered in pregnant women receiving long-term therapy with magnesium sulfate as compared with similar women not receiving magnesium sulfate to control preterm labor.
STUDY DESIGN: Thirty-nine women between 24 and 32 weeks' gestation, matched for age, race, and duration of bed rest, were enrolled. Indices of calcium homeostasis in serum and urine were measured serially, and bone mineralization of the distal radius was measured at 1 and 11 weeks post partum.
RESULTS: Magnesium therapy was administered for a mean duration of 26 ± 14 days and a cumulative dose of 1405 ± 963 gm. Serum concentrations of magnesium, phosphorus, and parathyroid hormone increased and those of calcium decreased from baseline values in the magnesium sulfate group and remained uniform throughout the 3-week investigation. The serum magnesium, phosphorus, parathyroid hormone, and calcium concentrations in the control group were unchanged during the study and differed significantly from those in the magnesium sulfate group ($p < 0.001$). Urinary output of magnesium, calcium, and copper was significantly greater in the magnesium sulfate group than in the control group throughout the study. Urinary losses of calcium in the magnesium sulfate group, approximately 800 to 900 mg/day, were substantial. Although radius bone density 1 week post partum did not differ between groups, the change in bone density from 1 to 11 weeks post partum was significantly lower in the magnesium sulfate group than in controls.
CONCLUSIONS: These data suggest that calcium homeostasis is altered during and after long-term magnesium sulfate therapy. The marked, prolonged urinary calcium losses may affect maternal bone mineralization. (Am J Obstet Gynecol 1992;167:45-51.)

Key words: Magnesium sulfate, calcium metabolism, bone mineralization

Tocolytic therapy with magnesium sulfate was originally proposed for 24 to 72 hours to delay preterm delivery until either the maximal effect of maternal glucocorticoid treatment on fetal lung maturation was achieved or β-sympathomimetic therapy was substituted.[1] This short-term $MgSO_4$ therapy is known to perturb calcium homeostasis, causing such imbalances as hypocalcemia and hypercalciuria.[2-5] These effects, reported in women with either pregnancy-induced hypertension or preterm labor, are reversible when $MgSO_4$ therapy is discontinued.[3, 4]

Long-term $MgSO_4$ tocolytic therapy recently has been described as safe and effective.[6] Tertiary care centers have adopted protocols for administering long-term $MgSO_4$ to delay preterm birth.[7] Scant published information exists regarding the effects of long-term $MgSO_4$ therapy on maternal calcium homeostasis. Two case reports raised concern about the safety of this therapy.[8, 9] Lamm et al.[8] reported on two newborn infants with metaphyseal lesions after 9 and 13 weeks, respectively, of maternal antenatal $MgSO_4$ therapy. Both infants manifested hypocalcemia and were considered by the authors to have congenital rickets. Cumming and Thomas[9] reported on an infant who had a discrete band of osteopenic metaphyseal bone. The infant, born to a mother receiving $MgSO_4$ for 13 weeks before delivery, had a normal serum calcium concentration and did not have rickets. The observations are consistent with experiments in vitro in which excess magnesium inhibits calcification of osteoid.[10] Maternal bone mineral abnormalities after long-term $MgSO_4$ therapy, however, have not been reported.

The cumulative effects of long-term $MgSO_4$ therapy

may differ quantitatively from the effects of short-term therapy. We hypothesize that because maternal calcium homeostasis may not adapt during long-term $MgSO_4$ therapy, metabolic perturbations could be detrimental to the mother. The objective of our study was to measure indices of calcium homeostasis and bone mineralization in hospitalized pregnant women in preterm labor receiving long-term $MgSO_4$ therapy.

Material and methods

Subject population. Pregnant women admitted to the labor and delivery units at St. Luke's Episcopal Hospital and The Methodist Hospital between 24 and 32 weeks' gestation were enrolled after informed written consent was obtained by one of the investigators. The $MgSO_4$ group comprised women in preterm labor in whom intravenous therapy with magnesium sulfate for more than 1 week and strict bed rest were anticipated. A control population, in which $MgSO_4$ was not used, comprised similar women in whom strict bed rest was anticipated for the obstetric indication of either placenta previa or preterm labor. Subjects were between 18 and 40 years of age; were free of systemic illness, chorioamnionitis, and medications known to affect calcium metabolism (e.g., diuretics, heparin, or anticonvulsants); and were not known to have fetal malformations or growth retardation. Groups also were matched for race and multiple gestations. The protocol was modified to exclude postpartum measurements of bone indices for subjects if $MgSO_4$ therapy was discontinued >1 week before delivery or if delivery occurred beyond 34 weeks' gestation. The protocol was approved by the institutional review boards for human research at the respective institutions.

The choice of tocolytic therapy was made by the attending obstetrician. $MgSO_4$ was administered as an intravenous loading dose of 6 gm over 30 minutes, followed by a maintenance dose of 2 gm/hr. The $MgSO_4$ infusion was titrated from 1.5 to 3.5 gm/hr, depending on uterine activity.

Study design. There were three sections of the study: measurements of indices of calcium homeostasis in serum, urine, and bone. Baseline (pre-$MgSO_4$ therapy or at enrollment in the control group) and weekly blood samples were obtained for analyses of magnesium, total and ionized calcium, phosphorus, parathyroid hormone, osteocalcin, alkaline phosphatase activity, albumin, and vitamin D metabolites. At the end of each week, urine was collected for 24 hours for the analyses of Mg, Ca, P, zinc, copper, hydroxyproline, and creatinine. Bone mineral content of the nondominant distal radius was measured 1 week post partum and at term-equivalent age (approximately 2 to 3 months post partum). Subjects maintained an activity diary throughout the hospitalization to assess the percentage of each day spent at bed rest.

Analytic methods. Magnesium, Ca, P, and creatinine in the serum and urine and alkaline phosphatase activity and albumin in serum were measured with colorimetric assays of the Cobas Fara autoanalyzer (Roche Diagnostics, Nutley, N.J.). Serum ionized calcium was measured by an ion selective electrode (Radiometer Corp., Copenhagen). Urinary Zn and Cu were determined by atomic absorption spectrophotometry. Urinary hydroxyproline was determined with a Beckman System 6300 amino acid analyzer (Beckman Instruments, Inc., Palo Alto, Calif.).[11] Radioimmunoassays were used to measure serum midmolecule parathyroid hormone and osteocalcin (INCSTAR, Stillwater, Minn.), 25-hydroxyvitamin D (Nichols Institute, San Juan Capistrano, Calif.) and 1,25-dihydroxyvitamin D.[12] Bone mineral content of the nondominant distal third of the radius was measured by single-photon absorptiometry (SP-2 scanner, Lunar Radiation Corp., Madison, Wis.).

Statistical analyses. Subject characteristics were analyzed by Student t test. The χ^2 and Fisher exact analyses were used to test dichotomous variables. The data were analyzed by repeated measures analysis of variance. Although some subjects were studied beyond 4 weeks, because of the dropout rate, only the first 3 weeks' data were tabulated. Average values for weekly (weeks 1 to 3) samples were reported when no changes were observed in repeated measurements over time. Regression analysis was used to investigate relationships between dependent and independent variables. The sample size was selected to detect a difference of 1 SD in outcome measures with a type I error of 0.05 and a power of 0.80. Data are tabulated as mean ± SD unless indicated otherwise.

Results

The characteristics of the 20 subjects in the $MgSO_4$ group and the 19 subjects in the control group were similar with respect to maternal age, parity, number of multiple gestations, racial distribution, length of gestation at enrollment and delivery, percentage of time at strict bed rest, and maternal anthropometric indices at delivery (Table I). Antenatal glucocorticoid therapy was used in 80% of the $MgSO_4$ group and 74% of the control group ($p > 0.10$). Premature rupture of membranes was documented in 50% of the $MgSO_4$ group and 32% of the control group ($p > 0.1$). Therapy with β-sympathomimetic agents was administered to 65% of $MgSO_4$ and 42% of control subjects ($p > 0.05$). The groups were distributed similarly with respect to season of enrollment. The mean duration of $MgSO_4$ therapy was 26 ± 14 days with a range of 8 to 63 days. The mean cumulative $MgSO_4$ dosage was 1405 ± 963 gm (range 342 to 4542 gm). The control group was hospitalized for 21 ± 14 days (range 7 to 56 days). The incidence and duration of lactation were similar be-

tween groups (median 5.5 weeks, range 0 to 36 weeks). Because of the study design and the right of subject refusal, some women participated in only two of the three sections of the study. Subject characteristics were similar between groups and resembled those of subgroups from the overall study population in whom serum (n = 32), urine (n = 27), or bone (n = 26) indices were measured.

Baseline serum Mg, total Ca, and P concentrations were similar between groups (Fig. 1). Serum Mg concentrations increased from baseline nearly threefold in the $MgSO_4$ group and were significantly greater in the $MgSO_4$ group than in the control group during 3 weeks of study ($p < 0.001$ by repeated measures analysis of variance). Serum concentrations of P increased and total Ca decreased in the $MgSO_4$ group from baseline, and each differed significantly between groups during 3 weeks of study ($p < 0.001$ by repeated measures analysis of variance for each). Serum concentrations of ionized Ca were similar at baseline (average 5.04 ± 0.08 mg/dl) in both groups. When measured at week 2 of study, serum concentrations of ionized Ca declined significantly in the $MgSO_4$ group (4.16 ± 0.44 mg/dl, $p = 0.006$) but remained unchanged in the control group. The serum total and ionized Ca concentrations were correlated ($r = 0.94$, $p < 0.001$); the decline in total Ca was attributed to the change in the ionized Ca fraction.

Serum parathyroid hormone concentrations were similar between groups at baseline. Serum parathyroid hormone concentrations increased from baseline in the $MgSO_4$ group and were significantly greater than those of the control group during the 3-week study ($p < 0.001$ by repeated measures analysis of variance, Fig. 2). Changes in parathyroid hormone concentrations from baseline were negatively correlated with changes in serum Ca concentrations ($r = -0.57$, $p = 0.002$); correlations with changes in serum Mg concentrations ($r = 0.31$, $p = 0.1$) did not reach statistical significance at the 0.05 level.

Serum osteocalcin concentrations were similar between groups; both groups had an increase from baseline (0.9 ± 1.5) to week 3 (1.2 ± 1.5 ng/ml, $p = 0.03$). Serum concentrations at baseline and during the 3-week study were similar between groups and over time for albumin (average of baseline and weekly concentrations, 3.0 ± 0.3 gm/dl), alkaline phosphatase activity (117 ± 56 IU/L), 25-hydroxyvitamin D (30 ± 16 ng/ml), and 1,25-dihydroxyvitamin D (56 ± 15 pg/ml). Serum concentrations of 25-hydroxyvitamin D did not change during the study interval but manifested significant seasonal variability. Greater concentrations of 25-hydroxyvitamin D were observed during summer (44 ± 11 ng/ml) than winter (22 ± 13 ng/ml, $p = 0.002$) months.

The 24-hour urinary excretion of Mg, Ca, P, Zn, Cu, hydroxyproline, and creatinine did not change during the 3-week study. The average value derived from the three weekly measurements of urinary Mg, Ca, and Cu output differed significantly between groups (Table II). There was nearly a threefold greater urinary output of Mg and Ca in the $MgSO_4$ group than in the control group. Creatinine clearance was similar between $MgSO_4$ and control groups (126 ± 42 vs 136 ± 35 ml/min, respectively). The percentage tubular reabsorption of P differed significantly between $MgSO_4$ and control groups (91% ± 4% vs 87% ± 4%, respectively, $p = 0.02$). The percent Ca reabsorption also differed significantly between $MgSO_4$ and control groups (93% ± 2% vs 98% ± 1%, respectively, $p < 0.001$). Serum osteocalcin concentrations correlated significantly with urinary copper output ($r = 0.40$, $p = 0.05$). The Mg dose correlated significantly with urinary output of Mg ($r = 0.51$, $p = 0.01$) and Ca ($r = 0.66$, $p = 0.001$). Urinary Ca output significantly correlated with urinary output of Mg ($r = 0.82$, $p < 0.001$), Ca ($r = 0.57$, $p = 0.002$), and P ($r = 0.49$, $p = 0.01$).

Bone density of the distal radius at 1 week post partum (701 ± 55 vs 675 ± 53 mg/cm²) was similar between $MgSO_4$ (n = 15) and control (n = 11) groups, respectively. No differences between groups were detected in either bone width or absolute bone mineral content at the site of measurement. Bone density was not correlated with body weight, height, race, age, or duration of hospitalization. Bone width was correlated with body weight ($r = 0.54$, $p = 0.005$) and height ($r = 0.43$, $p = 0.03$).

Because of the referral nature of the study population, traveling distance enabled only 15 women to return for follow-up measurements of bone mineralization at term-equivalent age. When measured at 11 ± 3 weeks post partum (42 ± 3 postmenstrual weeks), bone density was similar between groups. Repeated measures analysis of variance for bone density identified a sig-

Table I. Characteristics of subjects

Characteristic	*Group*

Significant differences ($p < 0.001$) between groups, determined by repeated measures analysis of variance, were observed during 3-week study but not at baseline.

returned for follow-up did not differ from the overall study group. Overall differences that had been observed between groups in serum and urine indices also were found in the subgroups.

Comment

Our study demonstrates that calcium homeostasis in pregnancy is affected by long-term intravenous $MgSO_4$ therapy. The alterations in serum and urine Mg and Ca parallel those reported after short-term (24 to 48 hours) $MgSO_4$ therapy.[3-5] Alterations in the latter case, however, are reversible after discontinuation of the $MgSO_4$ therapy.[3, 4] Serum concentrations of Ca decreased and those of P and parathyroid hormone increased and remained at the altered levels for the duration of the study. Urinary Mg, Ca, and Cu excretion remained significantly greater in the $MgSO_4$ group compared with the control group throughout the study interval. We did not examine these variables after the therapy was discontinued. During therapy, however, we observed no changes in the measured indices to indicate an adaptation (i.e., via diet or altered gastrointestinal nutrient absorption) to the therapy.[13]

The mechanism by which $MgSO_4$ therapy results in a decline in serum Ca concentration is unclear. Magnesium may inhibit or compete for common Ca reabsorptive sites in the loop of Henle.[14, 15] Our data demonstrated that the percent filtered Ca that was reabsorbed was significantly lower in the $MgSO_4$ group (93%) than in the control group (98%). We suggest therefore that the decline in serum Ca was a direct response to the elevated serum Mg and its action at the nephron. Similarly, the elevated serum P observed in the $MgSO_4$ group also may have resulted from hypermagnesemia and its effect on the reabsorption of P. We observed a greater percent tubular reabsorption of P in the $MgSO_4$ group (91%) than in the control group (87%), thus potentially explaining the greater serum P concentrations in the $MgSO_4$ group.

Our data do not support a role for parathyroid hormone in the genesis of hypocalcemia that occurs with hypermagnesemia. We found significantly increased parathyroid hormone secretion in the $MgSO_4$ group, which is contrary to other reports of short-term $MgSO_4$ therapy in which parathyroid hormone secretion was suppressed.[5, 16] Cruikshank et al.,[3] however, demonstrated that in women with preeclampsia the serum parathyroid hormone concentrations increase promptly and substantially in association with Mg-

induced decreases in serum ionized Ca concentrations. They commented that parathyroid hormone secretion is a protective response without which hypocalcemia would be manifested to a greater degree. Our data supported the latter contention. We found a significant correlation between the change in serum parathyroid hormone concentration and the change in serum Ca but not the change in serum Mg concentrations.

The urinary output of Ca and Mg in the $MgSO_4$ group was quantitatively similar to that reported during short-term therapy. Several investigations have demonstrated that urinary Mg excretion approximates 75% of the infused Mg dose during short-term studies and 99% if excretion is monitored beyond the infusion interval.[17,18] We observed that the quantity of Mg excreted was less than that infused. However, we monitored neither urinary excretion beyond the therapy interval nor the fetoplacental-amniotic fluid unit during therapy. We speculate, however, that a portion of the infused Mg may have been stored or deposited in the body.[13] Mg complexes with hydroxyapatite crystals and bone contents correlate positively with serum Mg concentrations.[13] We also considered that other divalent cations might be displaced by the presumed Mg deposition in bone. Approximately 30% of total body stores of zinc and 19% of copper are found in bone.[19] The explanation of the greater urinary losses of Cu in the $MgSO_4$ group is unknown. Further investigation is warranted.

The urinary losses of Ca, however, are a great concern. An increased daily loss of approximately 0.5 gm of Ca (difference between $MgSO_4$ and control groups) potentially might affect skeletal composition. If we assume that the total body Ca content is 900 gm in a young adult woman,[20] our subjects may have lost as much as 4% of total body Ca during a 60-day interval. Dietary intake and enhanced gastrointestinal absorption certainly restore a proportion of the Ca. Nevertheless, urinary losses of Ca approached the Recommended Dietary Allowance for Ca in pregnancy, 1,200 mg/day.[21] We speculate that usual Ca intakes during pregnancy would be inadequate to meet Ca needs and restore the Ca lost as a result of $MgSO_4$ therapy.

Osteocalcin is a sensitive marker for bone formation and bone remodeling. The serum concentration of osteocalcin rises in conditions characterized by high remodeling and declines when bone turnover is low.[22-24] We observed similar low serum concentrations of osteocalcin in both study groups. Although the reason for the modest elevation in serum osteocalcin in both groups is unclear, it may be associated with increased bone turnover in later pregnancy.[24] The relationship between osteocalcin and Mg has been studied.[25,26] In animal models serum osteocalcin concentrations increase markedly during $MgSO_4$ infusion. Those observations are consistent with studies in vitro demonstrating Mg displacement of osteocalcin from bone.[26] Whether similar Mg activity occurs during human pregnancy is unknown. We found no association between $MgSO_4$ and osteocalcin.

The similarities between groups in bone mineralization values 1 week post partum is paradoxic considering the large losses of Ca in urine in the $MgSO_4$ group. We speculate, however, that Mg displacement of other divalent cations may not have affected the measured bone density. We suggest that Mg may have been deposited in bone but did not affect bone turnover as evidenced by the lack of differences between groups in serum osteocalcin, alkaline phosphatase activity, or urinary hydroxyproline.

The apparent decline in bone density in the $MgSO_4$ subgroup from 1 to 11 weeks post partum was surprising but consistent with a slow loss of Mg deposited in bone during hypermagnesemia.[13] We sought other explanations for the differences in the rate at which bone density changed. We knew that subgroups had similar histories of lactation and medication usage. The observations should be interpreted cautiously, however, because of the small sample of women who were able to return for follow-up. Further evaluation of bone density changes should be undertaken.

Long-term $MgSO_4$ therapy produced changes in Ca homeostasis that were similar to those after short-term therapy. The duration of therapy did not appear to affect the magnitude of the changes in serum and urine indices; we observed no adaptation in these indices during long-term therapy. Nevertheless, the hypocalcemia was "stabilized" by parathyroid hormone activity on bone. Therefore $MgSO_4$ therapy may prevent extreme preterm delivery, but further evaluation of its effects, especially pertaining to bone mineralization, is warranted.

OBJECTIVES: The purpose of this study was to ascertain whether adverse fetal and/or neonatal effects occurred during nifedipine treatment of preterm labor and to assess maternal tolerance of nifedipine therapy in patients intolerant of a β-sympathomimetic agent

STUDY DESIGN: We undertook historic prospective review of medical records of 102 women admitted to an antepartum ward for treatment of preterm labor who received nifedipine. Data were collected regarding maternal side effects, fetal surveillance, and neonatal outcome.

RESULTS: The number and severity of reported maternal side effects were significantly reduced when patients were switched from terbutaline to nifedipine. No discontinuance of nifedipine occurred because of maternal side effects. Fetal surveillance testing and neonatal outcome data failed to reveal deleterious in utero effects of nifedipine.

CONCLUSIONS: Nifedipine was a well-tolerated and safe tocolytic in this population and warrants further investigation. (AM J OBSTET GYNECOL 1992;167:52-6.)

Key words: Nifedipine, β-sympathomimetic agents, tocolysis, preterm labor

Prematurity and low birth weight continue to be critical public health problems. In spite of marked reductions in infant mortality rates in the United States, the incidence of preterm birth has remained essentially unchanged in the past decade, at 8% to 10% of all births.[1] Tocolysis, the pharmacologic inhibition of uterine contractions, is currently the principal preterm birth preventive measure and will remain so until the etiology of preterm labor is better understood.

The tocolytic drugs most frequently used in the United States are the β-sympathomimetic agents, usually terbutaline or Food and Drug Administration–approved ritodrine.[2] Intravenous administration of these agents has a rapid tocolytic effect, and oral administration may be used for maintenance therapy. The β-sympathomimetic drugs, however, have significant and potentially serious maternal and fetal side effects (e.g., pulmonary edema, cardiac ischemia, and fetal cardiotoxicity[2, 3]). Less serious but more prevalent are the expected systemic side effects of tocolytic doses of β-adrenergic agonists, such as tachycardia, tremors, anxiety, palpitations, and insomnia.[4] Maternal intolerance of these side effects often requires reduction in dosage or discontinuance of therapy.[5]

Nifedipine, a calcium channel-blocking agent, has emerged as a potentially safer and better tolerated tocolytic agent.[6-8] Nifedipine inhibits smooth muscle contraction by impeding the flow of calcium across the muscle cell membrane.[9] Successful treatment of preterm labor with nifedipine has been reported.[10, 11] Maternal side effects were minimal in these 11 patients, consisting of mild transient headaches and a flushing sensation. In the single randomized trial published to date, nifedipine was found to be more efficacious and better tolerated than ritodrine.[6] Fetal surveillance during nifedipine therapy and neonatal outcome assessments revealed no evidence of adverse fetal effects in any of these studies.

The fetal safety of nifedipine was questioned, however, in several animal studies reported in the mid-1980s. In pregnant sheep and rhesus monkeys, where a continuous infusion of nicardipine* was administered, significant decreases in fetal arterial Po_2 and pH were found.[12, 13] To date, there have been no reports of adverse fetal effects of nifedipine in humans.

In 1987 nifedipine was introduced as an alternative tocolytic agent for Kaiser Permanente patients at St. Joseph Hospital. Initially, nifedipine was reserved for women who exhibited intolerance to therapeutic doses of other tocolytics, usually terbutaline. Close fetal surveillance was maintained after nifedipine therapy was

*Nicardipine is the intravenous analog of nifedipine.

begun to detect possible adverse fetal effects. Nifedipine appeared to be an effective tocolytic agent; it was well tolerated by patients and adverse fetal effects were not observed. However, in light of concern over fetal safety raised by some animal studies, a systematic review of all patients treated with nifedipine was undertaken. The objectives of this historic prospective study were as follows: (1) to ascertain whether adverse effects occurred among mothers and/or fetuses treated with nifedipine and (2) to assess nifedipine's usefulness in treating women in preterm labor who were intolerant of other tocolytics.

Material and methods

Study population. Medical records were reviewed for all women admitted to the St. Joseph Hospital antepartum ward with the diagnosis of preterm labor from Jan. 3, 1988, through March 31, 1989. Records of women admitted with conditions associated with preterm labor (such as pyelonephritis) were also reviewed. Medication records, physicians' orders, and discharge summaries were examined to identify patients who had ever received nifedipine. Subsequent hospital admissions, outpatient prenatal charts, and labor and delivery records were then reviewed for all patients identified as having been treated with nifedipine. Informed consent for the experimental usage of nifedipine was documented in all identified charts.

Patients with six or more regular uterine contractions in 1 hour who were admitted to the hospital for tocolysis were included in the study. Documentation of cervical change varied widely between clinicians and thus was not used as a criterion for inclusion.

Data collection. Data were abstracted from the medical records of all patients who had received nifedipine. The physician's progress notes and the nurse's notes were reviewed for reports of maternal side effects. Days of treatment were calculated from the first day of administration until the day of discontinuance. Clinical reasons given for discontinuing, changing, or adding tocolytics were coded and recorded. Prenatal records were reviewed for outpatient fetal surveillance data. The delivery record was the source of neonatal data. Gestational age was based on the obstetric estimate used in the medical record. The infant's medical record was reviewed only if an adverse outcome was reported.

Limitations. The reviewers were not blinded to the study objectives, but the first 30 charts (29.4%) were examined by two reviewers to establish interobserver reliability. Information regarding maternal side effects came from medical records only rather than directly from the patient. Thus this information is dependent on accurate recording in the nurse's and physician's notes. In general, the nurse's notes were the most informative. Their charting format would frequently directly quote the patient's statements regarding subjective symptoms. More serious maternal side effects, such as chest pain, tended to be more thoroughly documented than more minor complaints, and thus our methods were probably more sensitive for the severe side effects.

In this descriptive study the question of tocolytic efficacy was not addressed. Further, the lack of a comparison group treated with terbutaline only limits our conclusions.

Table I. Medication experiences of study population ($N = 102$)

Group	*No.*	*%*
Group 1. Terbutaline switched to nifedipine	51	50

Group 3. Nifedipine only	11	10.8
Group 4. Nifedipine combined with other tocolytic*	11	10.8
TOTAL	102	100

*Magnesium sulfate or indomethacin.

Results

A total of 119 patients were identified as having been treated with nifedipine for preterm labor during the 15-month study period. Seventeen patients (14.3%) were excluded from analysis because of incomplete information. Primigravid women constituted 33.3% of the study group, and the overall mean maternal age was 28 years.

Pregnancy complications in addition to preterm labor were experienced by 41 patients (40% of the study population). Twin gestations made up 18% of the entire study population but accounted for 38.3% of patients with complications. Second-trimester bleeding, usually placenta previa, was the next most frequent complication (21.3%), followed by maternal diabetes (8.4%).

Whereas there were varied patterns of tocolytic administration within the study population, four groups could be distinguished for descriptive purposes (Table I). Patients treated with terbutaline initially and then subsequently switched to nifedipine composed the largest group (group 1). Approximately 28% of the patients were treated with alternating doses of terbutaline and nifedipine (group 2), 11% received nifedipine alone (group 3), and 11% received nifedipine combined with another tocolytic agent* (group 4).

Of the 51 patients in group 1, 40 (78%) were switched to nifedipine because of adverse side effects of terbutaline. Table II compares the side effects reported by this group while they were receiving each of these tocolytics. Chest pain was experienced by 50% of the

*Side effects of terbutaline leading to change to nifedipine.

†Side effects reported after change to nifedipine.

‡The Sign test (True Epistat, 3rd ed. Tracy L. Gustafson) was used to compare side effects of these two tocolytic agents.

§Matched pairs of insufficient size for analysis.

‖Twelve patients (30%) reported a single side effect, whereas 28 patients (70%) reported two or more side effects.

¶More than one side effect was reported by two patients (5%), whereas 25 patients (62.5%) reported experiencing no side effects.

terbutaline group, with 12.5% showing ischemic electrocardiographic changes. Dyspnea (37.5%) and palpitations (37.5%) were the next most frequent side effects leading to discontinuance of terbutaline. Significant reductions in all of the side effects experienced with terbutaline occurred after a switch to nifedipine, except for nausea and vomiting, which remained about the same. While the patients were on a regimen of nifedipine, headache was the leading reported side effect (17.5%), and 62.5% reported no side effects.

Similar reductions in the number and severity of reported side effects are seen when all study patients treated with terbutaline and nifedipine are evaluated (Table III). Palpitations (41.2%), chest pain (39.2%), and dyspnea (29.4%) were again the most frequently reported side effects with terbutaline. Patients treated with nifedipine alone, as either the primary or secondary tocolytic, reported fewer side effects (30 vs 94), with nearly 52% reporting no side effects. Headache (19.4%), flushing (8.1%), and nausea and vomiting (6.5%) were the most common side effects reported in the nifedipine group. In no instance did maternal side effects necessitate discontinuance of nifedipine.

*Side effects reported while receiving terbutaline.

†Side effects reported while receiving nifedipine.

‡Thirty patients (58.8%) had two or more side effects.

§Thirty-two patients (51.6%) reported no side effects.

Fetal surveillance during tocolytic treatment, consisting of a nonstress test and/or a biophysical profile, was performed at least once in 79% of the singleton gestations and in 100% of the twin gestations. Of the 265 total surveillance tests performed, only one test result was abnormal. This nonreactive nonstress test was followed by a normal biophysical profile, and there was a normal neonatal outcome. The number of surveillance tests performed was directly related to the duration of tocolysis, with more tests performed on fetuses with longer exposures to nifedipine.

Interval fetal growth assessments were performed by ultrasonography on 65% of those exposed to nifedipine in utero, with adequate growth demonstrated in 92.3%. Of the 15 twin gestations monitored by serial ultrasonography, two sets of twins showed mild and one set showed moderate discordant growth; tocolytic therapy was discontinued. Three singleton gestations showed evidence of intrauterine growth retardation (IUGR). Maternal hypertension was present in one case, and there were known fetal anomalies in another, whereas the third fetus had no known risk factors for IUGR. Therefore five of the six fetuses with inadequate growth during tocolysis had other possible causative factors for IUGR.

Although there was no control group that had not received a tocolytic agent, pregnancies were extended 4.9 weeks from the time of preterm labor diagnosis. The mean estimated gestational age was 30.7 weeks at initiation of tocolysis and 35.6 weeks at discontinuance

of therapy. Overall, nearly 60% of the study group were delivered at term. The cesarean section rate for the study group was 26.5%, with only two procedures (2%) performed for fetal distress. Twin gestations had a 50% cesarean section rate in our study group.

Table IV contains neonatal outcome data for the entire study group. Mean birth weight was 2582 gm and mean gestational age was 36.8 weeks. Five infants (4.2%) had 5-minute Apgar scores <7, although only one had a venous cord pH <7.20. Assisted ventilation in the delivery room was required for 13 infants (10.8%). A total of 54 infants (45%) were taken from the delivery room to the neonatal intensive care unit, although this includes those neonates taken for observation only and then sent to the newborn nursery, a relatively standard procedure for preterm infants in this hospital. The previously described infant with congenital anomalies and IUGR was the only neonatal death in the study group. This infant died at 8 days of age from congenital heart and renal anomalies.

Of the 120 infants exposed to nifedipine, six infants (5%) were in the lst to 10th percentile of weight for age and thus met clinical criteria for IUGR. There were no infants in the severely growth-retarded (<1% weight for age) category. Overall, the weight percentiles were normally distributed.

Table IV. Outcome assessment for all neonates exposed to nifedipine in utero (n = 120)

Birth weight (gm)	
Mean ± SD	2582 ± 512

Assisted ventilation in delivery room‡ (No.)	13 (10.8%)
Neonatal intensive care unit§ (No.)	54 (45%)
Neonatal death (No.)	1‖ (0.8%)

*Includes 84 singletons and 36 twins.

†All had venous cord gas values determined; only one value was <7.20.

‡Bag-mask or intubation required.

§Taken to neonatal intensive care unit from delivery room (includes those taken for observation only).

‖Known congenital anomalies at initiation of tocolysis (dilated viscera, abnormal spine, intraabdominal calcifications) but with normal karyotype. Cardiac and renal anomalies diagnosed at birth were incompatible with life.

Comment

Our historic prospective study of 102 patients in preterm labor treated with nifedipine found that nifedipine is a better tolerated and safer tocolytic agent than terbutaline. Patients experiencing potentially serious side effects while receiving terbutaline (chest pain, tachycardia, ischemic electrocardiographic changes) had significant abatement of symptoms after they were switched to nifedipine and, in many cases, reported no subsequent side effects. The side effects reported most frequently with nifedipine were headache, constipation, and nausea, a dramatic contrast to those reported by patients receiving terbutaline. When one considers that the potentially fatal cardiorespiratory complications seen with β-sympathomimetic therapy are often preceded by side effects such as tachycardia, dyspnea, and chest pain, the difference in side effect profiles between these two agents becomes even more meaningful.

Clearly, the fetal effects of nifedipine have been the major concern regarding its use for preterm labor. The only alleged presumptive danger to the fetus has been reported in animal studies of uterine perfusion and fetal oxygenation.[14,15] In this study there were 265 fetal surveillance tests performed during nifedipine therapy, with only one abnormal test. Because of our limited sample size, there may have been insufficient power to detect adverse fetal effects of nifedipine. However, the absence of evidence indicating hypoperfusion or deoxygenation of nifedipine-exposed fetuses was reassuring.

Ritodrine was approved for use in treating preterm labor in 1980 and has since become a first-line tocolytic agent. In the ensuing decade negligible improvement was noted in the rate of preterm birth, yet maternal, fetal, and neonatal morbidity and mortality attributable to ritodrine and other β-sympathomimetic agents have been recorded. The psychotropic changes induced by the β-sympathomimetic agents, such as anxiety and insomnia, cause enormous maternal discomfort and are the exact opposite of those desired—rest and relaxation for prolonging pregnancy. In our study nifedipine was used as a tocolytic agent with no maternal morbidity, minimal maternal discomfort, and no demonstrable deleterious fetal or neonatal effects.

A randomized prospective trial of nifedipine is needed to compare its efficacy with that of other standard tocolytic agents. In such a study close fetal surveillance and detailed neonatal and infant follow-up will be important. Calcium channel blockers show great promise as tocolytic agents for both mother and fetus.

Nonimmune hydrops fetalis associated with maternal infection with syphilis

John R. Barton, MD,[a] Edwin M. Thorpe, Jr., MD,[b] David C. Shaver, MD,[b] W. David Hager, MD,[a] and Baha M. Sibai, MD[b]

Lexington, Kentucky, and Memphis, Tennessee

Intrauterine infection with syphilis was diagnosed by reactive maternal serologic studies, ultrasonographic findings, and exclusion of other causes in three hydropic fetuses at 31, 34, and 35 weeks' gestation. With penicillin therapy and preterm delivery all infants survived through the perinatal period. Intrauterine infection that follows syphilis is a potentially treatable cause of nonimmune hydrops. (AM J OBSTET GYNECOL 1992;167:56-8.)

Key words: Nonimmune hydrops, syphilis, pregnancy

The dramatic increase in the incidence of early syphilis in the United States has lead to a concomitant rise in reported cases of congenital syphilis and nonimmune hydrops associated with maternal infection. Earlier reports of nonimmune hydrops associated with syphilis, which have been limited to developing countries, demonstrate increased perinatal mortality. Chawla et al.[1] in Zimbabwe described three cases with a 100% neonatal mortality, whereas in Singapore, Tan[2] reported on four patients with a 75% mortality. We report three cases of nonimmune hydrops fetalis associated with maternal infection with syphilis managed with an aggressive protocol; all neonates survived.

Case reports

Case 1. A 21-year-old woman, gravida 2, para 1, with uncertain menstrual dates and no history of syphilis treatment was referred in preterm labor. Antenatal laboratory screen 3 days before admission was significant for a reactive rapid plasma reagin titer of 1:32; she denied previous treatment for syphilis. Penicillin for early latent syphilis was initiated before transfer. The patient's blood type was O negative, and antibody

Table I. Initial newborn laboratory values

	Case 1	*Case 2*	*Case 3*	*Normal*
White blood cell count ($\times 10^9$/L)	95.1	31.4	6.8	5-21
Hemoglobin (gm/dl)	6.0	4.5	12.8	15.5-18.9
Hematocrit (%)	19.9	13.2	39.7	42-56
Platelet count ($\times 10^9$/L)	53	31	67	140-290
Fetal rapid plasma reagin titer	1:16	1:16	1:128	Nonreactive
Fetal microhemagglutination assay for antibodies to *T. pallidum*	Positive	Positive	Positive	Negative
Total protein (mg/dl)	2.2	3.6	4.8	4.6-8.0
Albumin (mg/dl)	0.9	1.8	2.4	3.0-5.5
Immunoglobulin M (mg/dl)	101	172	—	0-25

screen was negative. Ultrasonographic evaluation revealed an intrauterine pregnancy at 31 week's gestation with fetal ascites, marked generalized subcutaneous edema, and hydramnios. There were no other fetal structural abnormalities, and a fetal echocardiogram was normal. On admission a maternal Kleihauer-Betke test was negative, repeat maternal rapid plasma reagin titer was 1:128, and a microhemagglutination assay for antibodies to *Treponema pallidum* was positive. The amniotic fluid lecithin/sphingomyelin ratio was mature. Rapid karyotype from blood obtained by cordocentesis was normal. The patient underwent cesarean section for breech presentation and was delivered of a 3540 gm female infant with Apgar scores of 2 and 3 at 1 and 5 minutes, respectively. Initial laboratory values are summarized in Table I. The neonatal course was significant for persistent pulmonary hypertension treated with hyperventilation alone. The infant remained on a ventilator for 14 days. Radiographic examination revealed metaphyseal rarefaction in all long bones. The infant received 21 days of intravenous penicillin G therapy and was discharged home at 43 days of life.

Case 2. An 18-year-old woman, gravida 2, para 0, abortus 1, at 35 weeks' gestation had fetal ascites and subcutaneous edema noted on routine ultrasonographic evaluation. There were no other structural abnormalities. The maternal blood type was B positive, and an antibody screen was negative. Rapid plasma reagin titer was reactive (1:64) and microhemagglutination assay for antibodies to *T. pallidum* was positive; she denied previous treatment for syphilis. External monitoring of the fetal heart rate was nonreactive with repetitive late decelerations. Because of the gestational age (35 weeks) and the nonreassuring fetal assessment, a primary cesarean section was performed. A 2700 gm female infant was delivered with Apgar scores of 0 and 1 at 1 and 5 minutes, respectively. Paracentesis was performed in the delivery room because of neonatal respiratory compromise from the ascites. Initial neonatal laboratory values are summarized in Table I. The infant required 4 days of mechanical ventilation, received 21 days of intravenous penicillin G, and was discharged home on the twenty-second day of life. Follow-up of the infant at 6 months showed a nonreactive rapid plasma reagin titer.

Case 3. A 21-year-old woman, gravida 1, para 0, was seen at 34 weeks' gestation without prenatal care. Antenatal laboratory screen was significant for a reactive rapid plasma reagin titer (1:32) and a positive microhemagglutination assay for antibodies to *T. pallidum.* Maternal blood type was A positive, and an antibody screen was negative. Fetal ultrasonographic examination revealed ascites, pericardial effusion, generalized subcutaneous edema, and hydramnios. Maternal treatment with penicillin was initiated. An amniocentesis noted a mature lecithin/sphingomyelin ratio (6.8:1). Although initially reassuring, the fetal heart rate tracing became nonreactive, and a contraction stress test was positive. A 2530 gm male infant was delivered by cesarean section with Apgar scores of 8 and 9 at 1 and 5 minutes, respectively. Initial neonatal laboratory values are summarized in Table I. Radiographic examination revealed metaphyseal lucent bands in all long bones. The infant received 12 days of intravenous penicillin G, and the neonatal course was significant for apnea of prematurity necessitating home monitoring. The infant was subsequently discharged at 30 days of age.

Comment

Nonimmune hydrops fetalis is associated with a myriad of maternal and fetal medical conditions. Because of the extremely poor perinatal outcome, management of pregnancies complicated by this disorder should be dictated by specific cause. It is important to consider the feasibility of treatment as determined by the cause before aggressive management is initiated. Congenital syphilis is a potentially treatable cause of nonimmune hydrops and warrants intravenous antibiotic therapy and delivery. If the fetus is extremely premature, high-dose maternal penicillin therapy is indicated until a gestation compatible with survival is achieved.

Current recommendations for the treatment of syphilis complicating pregnancy emphasize the role of penicillin as the drug of choice. Published studies of treatment of maternal infection with nonpenicillin regimens

report unacceptably high failures in preventing congenital syphilis. Patients who report penicillin allergy should undergo testing for confirmation, then desensitization, followed by treatment with penicillin.

The optimal treatment regimen for nonimmune hydrops caused by maternal infection with syphilis has not been determined. Treatment with penicillin, particularly in early syphilis, carries the risk of a maternal Jarisch-Herxheimer reaction, which may further compromise a severely affected fetus. Antenatal testing therefore is critical for monitoring fetal distress in response to both nonimmune hydrops and complications of treatment of syphilis.

Suppression of 24-hour cholecystokinin secretion by oral contraceptives

Roger Karlsson, MD,[a] Angelica Lindén, MD, PhD,[b] and Bo von Schoultz, MD, PhD[b]
Umeå and Stockholm, Sweden

Weight gain is a common side effect during oral contraceptive use. The secretion of the satiety hormone cholecystokinin was recorded for 24 hours in women before and during treatment with oral contraceptives. During treatment serum profiles of cholecystokinin were clearly suppressed, which might be related to increased appetite and weight gain. (Am J Obstet Gynecol 1992;167:58-9.)

Key words: Oral contraceptives, cholecystokinin, secretory profile

Weight gain is a well-known side effect during hormonal contraception, in particular during use of high-dose progestins. The mechanism is incompletely understood, but a stimulation of appetite seems to be an important component. Recent research has emphasized the role of neuropeptides in the regulation of food intake. The gut-brain peptide cholecystokinin is released in response to a meal and has been suggested to be a physiologic satiety factor.[1] In the current study the 24-hour serum profiles of cholecystokinin were monitored in women before and during oral contraceptive use.

Material and methods

Subjects. Complete 24-hour serum profiles of cholecystokinin were established in nine healthy women attending the local health care center for contraceptive counseling. Their mean age was 25 years (range 22 to 31). The women were evaluated before oral contraceptive use (five of them in the follicular phase and four in the luteal phase of the menstrual cycle) and after 2 to 3 months of treatment with monophasic, combined oral contraceptives (30 μg ethinyl estradiol–150 μg desogestrel or 30 μg ethinyl estradiol–150 μg levonorgestrel). The study was approved by the local medical ethics committee.

Blood sampling. Venous blood samples were obtained with a nonthrombogenic blood withdrawal system. A portable, battery-charged excentric pump (Cormed, Medina, N.Y.) was used to obtain continuous sampling from an antecubital vein through heparin-coated polyvinyl chloride tubing (Durascan Medical Products, Odense, Denmark) during normal daily activities. The activity and food intake of subjects were recorded but in no way restricted. Throughout 24 hours collecting tubes were changed at 30-minute intervals, and approximately 5 ml blood was collected in each 30-minute period. Blood samples were centrifuged free of formed elements, and equal amounts of sera were removed and pooled into one sample for every 2-hour period before being stored at −20° C.

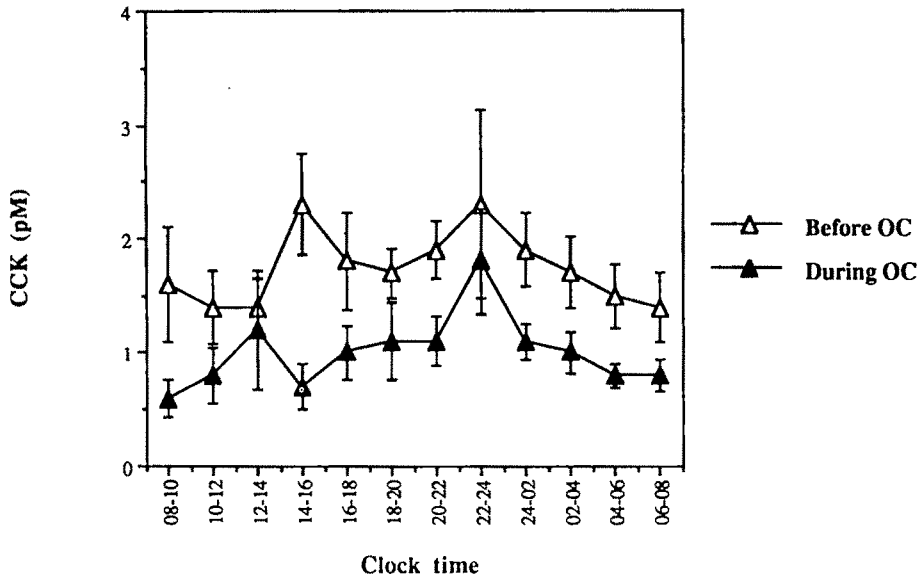

Fig. 1. Serum 24-hour profiles of cholecystokinin *(CCK)* in nine women before and during treatment with oral contraceptives *(OC)*. Values are means ± SEM.

Assay. Before cholecystokinin analysis, sera were extracted and concentrated on C18 Sep-Pak cartridges (Waters Associates, Milford, Mass.). Cholecystokinin was eluted with a mixture of 5 ml 50% acetonitrile and 50% 0.1% acetic acid. Eluted samples were dried and then reconstituted in assay buffer for determination of cholecystokinin with a previously described sensitive and highly specific radioimmunoassay[2] with the modification of using sulfated cholecystokinin-8 as the tracer. Intraassay and interassay coefficients of variations were 4.0% and 10.6%, respectively, and the detection limit of the assay was 2 pmol/L. However, measurement of tenfold lower concentrations of cholecystokinin was made possible by a concentration of the serum samples.

Statistical analysis. Data are presented as means ± SEM. The effect of treatment with oral contraceptives was evaluated with two-factor analysis of variance with repeated measures.

Results and comment

The 24-hour serum profiles of cholecystokinin before and during oral contraceptive use are illustrated in Fig. 1. At all points throughout the 24-hour period cholecystokinin values were lower when women were using oral contraceptives (overall effect $p < 0.001$).

Oral contraceptives are widely used by women for family planning purposes. Still, there is considerable uncertainty about the significance of the many metabolic changes that have been observed during treatment. Weight gain and mood changes have been reported with frequencies varying between 5% and 15% of users. There is increasing evidence that progestins have behavioral effects in women. Progestins may stimulate appetite and in some women cause mood changes, which also are associated with alterations in appetite and food intake. However, the mechanisms of action are not fully explored.

Animal experiments have clearly demonstrated the satiety-inducing effects of peripherally and centrally administered cholecystokinin.[1] Furthermore, the use of recently developed specific cholecystokinin receptor antagonists has provided evidence that endogenous cholecystokinin plays a physiologic role in food intake regulation. Cholecystokinin suppresses food intake not only in experimental animals but also in humans. Recent studies have shown disturbances in meal-related cholecystokinin secretion in eating and affective disorders.[1]

The current results clearly demonstrate a suppression of 24-hour serum levels of cholecystokinin during oral contraception. This might well relate to increased appetite and weight gain in individual women. Further studies are clearly indicated to evaluate the significance and mechanism behind this effect.

Delayed endometrial maturation induced by daily administration of the antiprogestin RU 486: A potential new contraceptive strategy

Marcelo C. Batista, MD,[a] Tannia P. Cartledge, RN,[b] Ann W. Zellmer, RN,[b] Maria J. Merino, MD,[c] Constantine Axiotis, MD,[c] D. Lynn Loriaux, MD, PhD,[a] and Lynnette K. Nieman, MD[a]

Bethesda, Maryland

OBJECTIVE: Our objective was to determine if a progesterone antagonist might interdict the development of a secretory endometrium.

STUDY DESIGN: Eleven normally cycling women not at risk for pregnancy received RU 486 (1 mg/day orally) or placebo throughout one menstrual cycle in a randomized, double-blind, crossover fashion. Estradiol, progesterone, and placental protein 14 were measured every 3 days; luteinizing hormone was measured until the midcycle surge was detected. An endometrial biopsy was performed on luteal phase day 7 to 9 and interpreted with Noyes' criteria. Differences between treatment groups were analyzed by the Student *t* test.

RESULTS: RU 486 delayed ovulation, retarded endometrial maturation, and reduced peak levels of placental protein 14 without affecting gonadal steroid production. The abnormalities in endometrial morphology and function are similar to those seen in infertile women with luteal phase defects.

CONCLUSION: We hypothesize that this regimen of antiprogestin administration may prevent implantation and offer a novel strategy for fertility control. (Am J Obstet Gynecol 1992;167:60-5.)

Key words: RU 486, antiprogestins, contraception, endometrium

It is estimated that the world's population will double by 2050 AD.[1] In a time of limited resources birth control offers the only solution to an otherwise inevitable Malthusian crisis. The United States population has increased by only a modest 10% in the past decade,[1] in part because of a high abortion rate. Many would prefer that population growth be controlled by contraception rather than abortion. However, this goal is compromised by a relatively limited choice or availability of contraceptive technologies. Additionally, there has been a decrease in new research and development initiatives in this field, in spite of the recent emergence of a number of potential approaches. Compounds that block progesterone action represent one such avenue. Progesterone is required for normal reproductive function in women, because it engenders the development of a secretory endometrium and enables the implantation of an embryo.[2] A progesterone antagonist may thus, in theory, impede endometrial development and prevent pregnancy without disrupting other aspects of reproductive function. We previously tested this hypothesis with a large, single midluteal phase dose of RU 486, a 19-norsteroid that antagonizes progesterone action at the receptor level.[3] Although this approach consistently prevented pregnancy in rhesus monkeys,[3] a single late-luteal phase dose was less effective in clinical trials in women.[4] In contrast, our recent studies in guinea pigs demonstrated that daily administration of RU 486 (0.8 to 2.5 mg) throughout an estrous cycle prevented pregnancy in otherwise sexually active, ovulatory animals.[5] Taken together, these results suggested that progesterone blockade of the endometrium would be more effective if initiated earlier in the luteal phase and that a small daily dose of RU 486 might have a cumulative antinidatory effect in women.

We therefore investigated whether RU 486 given at a small daily dose (1 mg) throughout the menstrual cycle could delay endometrial maturation without suppressing steroidogenesis or ovulation in women not at risk for pregnancy. A daily schedule of administration would, in theory, induce a hostile endometrium before the expected time of implantation, regardless of the variability in a given woman's cycle. It would also avoid the difficulty of identifying a specific menstrual cycle day to take the compound. We assessed the develop-

ment of the endometrium both morphologically, by evaluation of endometrial histology, and functionally, by measurement of serum levels of placental protein 14.[6] Placental protein 14 is synthesized by the progesterone-induced secretory endometrium and is a potent inhibitor of lymphocyte activation, which suggests an important immunomodulatory role during implantation and early pregnancy.[6, 7] Serum placental protein 14 concentrations increase during the late luteal phase and peak at the onset of menses.[6]

Material and methods

Subjects. Eleven healthy nonpregnant women (mean age 31.0 ± 1.5 years, range 23 to 38 years) volunteered for the study. Nine had previously been pregnant and none had a spontaneous abortion. All had regular menstrual cycles of 26 to 30 days and were between 86% and 126% of ideal body weight (mean 64.0 ± 2.3 kg, range 50 to 75 kg). No subject gave a history of galactorrhea, unusual dietary habits, or strenuous exercise, and none had used hormonal contraceptives or intrauterine devices during the previous 6 months. All women used barrier methods or abstained from sexual intercourse during the study. The menstrual cycle before initiation of the protocol was 26 to 30 days in length; ovulation and normal luteal function were confirmed by measuring serum progesterone on three different days of the luteal phase.[8] Pregnancy was excluded by a serum β-human chorionic gonadotropin concentration <2.0 ng/ml (the threshold for detection of pregnancy in this assay) within 48 hours before the onset of RU 486 or placebo administration.

The study was approved by the United States Bureau of Drugs and Biologics and the Clinical Research Subpanel of the National Institute of Child Health and Human Development. Informed consent was obtained from each subject.

Protocol. The study consisted of two treatment cycles separated by one or two rest cycles. Each woman received either RU 486 at a daily oral dose of 1 mg or placebo during one treatment cycle in a randomized, double-blind, crossover fashion. Treatment was started on the first or second day of menses and continued until cycle day 25 or the day of the endometrial biopsy, whichever came last. Hormonal events of the two treatment cycles were monitored by measurements of plasma luteinizing hormone (LH) (daily from day 9 until the midcycle surge) and serum estradiol and progesterone (every 3 days). The endometrium was evaluated by determination of serum placental protein 14 concentrations (every 3 days) and by histologic dating of an endometrial biopsy obtained 7 to 9 days after the LH surge. Electrolytes, liver and renal function tests, and cell blood counts were evaluated at the beginning and end of each treatment cycle. Progesterone was measured on days 18, 21, and 24 of the immediate posttreatment cycle to assess luteal function.[8] Women kept daily records of menstrual flow, premenstrual symptoms, dysmenorrhea, and any unusual symptoms, including intermenstrual bleeding and decreased libido, during the treatment and recovery cycles.

Endometrial biopsy. An endometrial biopsy was scheduled prospectively and obtained 7 to 9 days after the midcycle LH peak was detected by a rapid plasma assay. Specimens were taken from the uterine fundus with the Pipelle curet (Prodimed, Neuilly-en-Thelle, France). Chronologic dating of the biopsies was assigned prospectively by counting forward from the day of the LH peak (taken as cycle day 14) until the day of the biopsy.[9] At the end of the study all biopsies were reviewed independently by two pathologists (M.M. and C.A.), who had no knowledge of the day of the biopsy or the treatment instituted in a given cycle. Histologic dating was done according to the criteria of Noyes et al.[10] with a 2-day reading, e.g., secretory day 22 to 23. Endometrial maturation was assessed by correlating the chronologic date with the most advanced histologic date of the biopsy, in keeping with Noyes et al.'s recommendation that dating should rely primarily on the morphology of the most advanced portion or feature of the endometrium.[10] A biopsy was considered delayed when the histologic dating lagged more than 2 days behind the chronologic dating and normal when these dates were within 2 days of each other.[11]

Preparation of RU 486 and placebo. Capsules containing either 1 mg of micronized RU 486 (Roussel-UCLAF, Paris) or placebo were prepared by the Pharmaceutical Development Service of the National Institutes of Health.

Hormone assays. Measurements of serum estradiol[12] and progesterone[13] and rapid determinations of plasma human chorionic gonadotropin and LH (Diagnostic Products Corporation, Los Angeles) were obtained by radioimmunoassay. The intraassay and interassay coefficients of variation were below 12% and 17%, respectively, for all hormones.

Serum placental protein 14 was measured by radioimmunoassay according to the method of Bolton et al.[14] with minor modifications. The purified placental protein 14 standard (lot no. 120/135) and antiserum (lot no. 201ZA) were kindly provided by Dr. Hans Bohn (Behringwerke AG, Marburg, Germany). Radioiodination of placental protein 14 was carried out by lactoperoxidase, followed by purification of the tracer in Sephadex and concanavalin A-Sepharose columns.[14] The anti–placental protein 14 antibody was used at a dilution of 1:16,000; its specificity has been described elsewhere.[14] Bound and free hormone were separated by adding goat anti-rabbit antiserum and polyethylene glycol. All placental protein 14 samples were measured

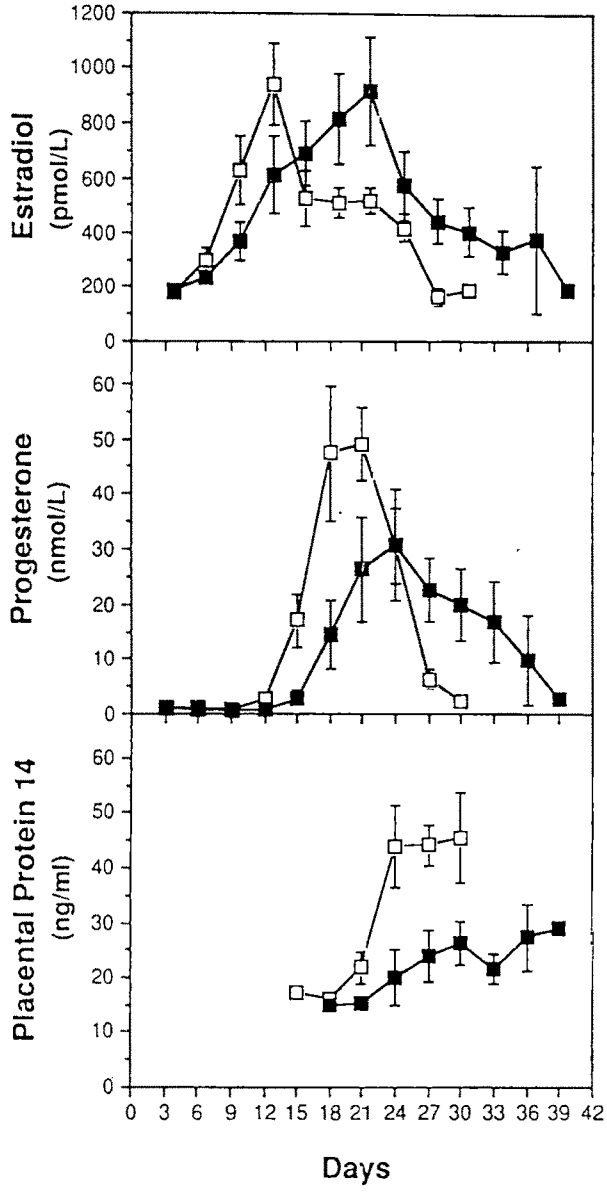

Fig. 1. Effects of RU 486, 1 mg/day *(closed squares)*, and placebo *(open squares)* administration on mean (±SE) levels of estradiol, progesterone, and PP14 in nine ovulatory women. Both medications were given throughout one menstrual cycle. Day 1 corresponds to first day of menses.

in the same assay; the detection limit was 4 ng/ml and the intraassay variation was 6.7%, 4.4%, and 4.4% at concentrations of 31.0, 59.4, and 87.0 ng/ml, respectively.

Analysis. The follicular phase was defined as days elapsed between the onset of menses and the day of the LH peak. The luteal phase was defined as days after the LH peak until the day before the next menses. The integrated secretion of estradiol or progesterone was defined as the sum of all values obtained during a treatment cycle. Results are presented as mean ±SE. Except as noted, the Student t test for paired variables was used to compare results between groups. Differences were considered significant at $p < 0.05$.

Table I. Effects of RU 486 administration (1 mg/day) throughout one menstrual cycle on the duration of the follicular and luteal phases in nine ovulatory women

Treatment	*Cycle length (days)*	*Follicular phase (days)*	*Luteal phase (days)*
Placebo	25.0 ± 0.6	13.0 ± 0.5	12.0 ± 0.6
RU 486	31.4 ± 1.3*	18.9 ± 1.4*	12.6 ± 0.7

*Significantly different compared with placebo ($p < 0.01$).

Results

Effects of RU 486 on cycle length. Two women were excluded from all data analysis. One subject had dyssynchronous endometrial biopsies obtained on the seventh day after the LH peak in both treatment cycles. Because the glandular epithelium and stromal tissue were at different stages of endometrial maturation, it was not possible to assign an overall histologic date to these specimens. In the other woman, the LH surge was suppressed completely during RU 486 administration, and thus no biopsy was obtained. Ovulation probably occurred at least 5 days after RU 486 was discontinued, when progesterone concentrations rose above 3.2 nmol/L. In contrast, her cycle was normal during placebo administration; the LH surge occurred on cycle day 15 and a normal biopsy was obtained on post-LH surge day 8.

RU 486 delayed the midcycle LH surge and prolonged the follicular phase by 1 to 11 days in the remaining nine women (Table I). In contrast, the compound did not change the duration of the luteal phase (Table I). As result, the mean length of the entire cycle increased by an average of 6 days in women receiving RU 486.

Effects of RU 486 on ovarian steroidogenesis. Follicular-phase estradiol concentrations increased at a slower rate and peaked later during RU 486 compared with placebo treatment (Fig. 1). Although not readily apparent from Fig. 1 because of variability of the day on which maximum values occurred, peak preovulatory estradiol levels were significantly higher in the RU 486 (1292 ± 121 pmol/L) than in the placebo group (1098 ± 106 pmol/L, $p = 0.0060$). However, the integrated estradiol secretion was similar in both treatment cycles (4633 ± 705 vs 3495 ± 367 pmol/L/day, respectively). Luteal-phase progesterone concentrations (>3.2 nmol/L) also occurred later during RU 486 treatment and parallelled the delay in the LH surge induced by this compound (Fig. 1). There were no differences in the peak concentration or integrated se-

cretion of progesterone during RU 486 (47.1 ± 8.9 nmol/L and 129.1 ± 20.3 nmol/L/day, respectively) and placebo administration (59.1 ± 10.5 nmol/L and 131.4 ± 10.5 nmol/L/day).

Effects of RU 486 on endometrial maturation. The RU 486 group had a significantly larger difference between histologic and chronologic dating of the biopsy when compared with placebo (Table II). Six of the nine women included in the data analysis had a delayed biopsy during RU 486 treatment, as opposed to none during placebo administration ($p = 0.0027$, χ^2 analysis). In these six women the histologic dating lagged 3 or 4 days behind the chronologic dating of the biopsy. These dates were within 2 days of each other in the remaining three women.

Peak placental protein 14 concentrations (Fig. 1) occurred around the onset of menses and were significantly lower after RU 486 (34.0 ± 3.3 ng/ml) than placebo treatment (49.2 ± 6.5 ng/ml, $p = 0.0103$).

Other effects of RU 486. Premenstrual symptoms, dysmenorrhea, electrolytes, liver and renal function tests, and cell blood counts were unaffected by RU 486 treatment. Likewise, no unusual symptoms, including intermenstrual bleeding and altered libido, were noted.

Both the duration of menses (4.0 ± 0.4 vs 5.9 ± 0.7 days, $p = 0.0492$) and the length of the posttreatment cycle (26.9 ± 0.7 vs 29.0 ± 0.4 days, $p = 0.0026$) were reduced significantly after RU 486 compared with placebo administration. The sum of three luteal progesterone measurements exceeded 47.7 nmol/L in all recovery cycles.

Table II. Effects of RU 486 administration (1 mg/day) throughout one menstrual cycle on endometrial maturation in nine ovulatory women

	*Endometrial maturation**	
Treatment	*Pathologist M.M.*	*Pathologist C.A.*
Placebo	0.2 ± 0.6 (−2 to 3)†	0.3 ± 0.6 (−2 to 3)

*Lag in days between histologic and chronologic dating of an endometrial biopsy, as judged by two different pathologists (M.M. and C.A.).

†Range.

‡Significantly different compared with placebo ($p \leq 0.02$).

Comment

Our data show that administration of the antiprogestin RU 486 at a small daily dose (1 mg) can induce a functional state of progesterone deficiency without suppressing ovarian steroidogenesis or ovulation. Six of the 10 women who ovulated during RU 486 administration had delayed endometrial morphologic characteristics, whereas one exhibited dyssynchrony between glandular and stromal tissue. Although endometrial maturation was assessed only by the histologic criteria of Noyes et al.,[10] it is possible that morphometric analysis, which appears to be more precise,[15] of the endometrium would show abnormalities in the remaining three women who had normal biopsies during RU 486 treatment according to the former method. The suppressed serum concentrations of placental protein 14, a glycoprotein synthesized by the progesterone-induced secretory endometrium that has been proposed as a marker of endometrial function,[6] provides additional evidence for the antiprogestin effects of RU 486 on the endometrium. The pharmacologically induced abnormalities in endometrial morphology and function observed in this study are similar to those seen in infertile women with luteal-phase defects. This condition, most often due to deficient progesterone secretion, is typically associated with a delayed endometrial biopsy.[11] Although placental protein 14 concentrations have not been reported in women with luteal-phase defects, an immunologically identical protein, progestagen-dependent endometrial protein,[6] was shown to be reduced in this population.[16] Thus the endometrial abnormalities observed in the present study may reflect an intrauterine environment hostile to implantation.

The time course of endometrial maturation during RU 486 administration deserves further investigation. The findings of the Carnegie Institute that both the embryo and the endometrium are at luteal phase day 6 to 8 at the beginning of implantation in cycles resulting in conception suggest that successful initiation of this process requires a relative synchrony between the development of the embryo and the maturation of the endometrium.[17] These results influenced our decision to examine the endometrium at the expected time of implantation relative to the LH surge and embryo development rather than at a later time in the luteal phase, as is often done in clinical practice.[11] Also, histologic dating of the endometrium is more precise and agrees more closely with chronologic dating when specimens are obtained in the midluteal than in the late luteal phase.[18, 19] It is possible, however, that a delayed endometrium 7 to 9 days after the LH surge might later mature and sustain implantation, if the blastocyst could wait until maturation occurred. Studies of women with ovarian failure undergoing assynchronous transfer of donor embryos suggest that implantation can occur if the endometrium is no more than 2 days delayed, as assessed by an endometrial biopsy performed in a previous cycle.[20] Because the endometrium in these recipients is prepared with exogenous steroids and the embryo develops in vitro until transferred, it is unclear whether these findings can be extrapolated to the blas-

tocyst-uterine relationship in natural cycles resulting in conception.

Although RU 486 administration delayed the LH surge and ovulation by an average of 6 days, the length of the follicular phase and the total duration of the RU 486 cycle remained within the normal range for the adult female population.[21] The prolongation of the follicular phase may reflect partial suppression of folliculogenesis induced by RU 486, as suggested by the slower rise in follicular-phase estradiol concentrations. This may be mediated through either gonadotropin inhibition, a direct ovarian effect, or a combination of both.[22, 23] However, the significantly higher preovulatory estradiol levels observed during RU 486 administration suggest that another late follicular phase mechanism contributes to the delay in the gonadotropin surge. Because progesterone concentrations start to rise just before the LH surge and may trigger this process, progesterone antagonism induced by RU 486 at midcycle may delay this event.[24]

RU 486 administration did not change the duration of the luteal phase. Both RU 486 and placebo cycles had a 12-day luteal phase, which is slightly shorter than usually seen in normally cycling women.[25] This may be due to the luteolytic effect of prostaglandins released during the endometrial biopsy or to partial disruption of the endometrium caused by this procedure.[10]

Although follicular-phase estradiol concentrations increased at a slower rate during RU 486 treatment, the integrated estradiol secretion was similar to that seen during placebo administration, indicating that the RU 486 regimen did not cause a low estrogenic state. Likewise, RU 486 did not alter corpus luteum function, as evidenced by similar peak levels and integrated secretion of progesterone in both treatment cycles. Although the blood sampling frequency of every 3 days has been advocated as a good index of luteal function,[8] this approach may not detect subtle changes over the entire cycle or in an event that occurs over a short time span, such as the preovulatory peak of estradiol concentrations.

RU 486 can thus preserve ovulation, steroidogenesis, and the timing of the menstrual cycle when given at a daily dose of 1 mg. This contrasts with the complete inhibition of follicular development, steroidogenesis, and ovulation and also with the luteolysis seen with higher doses.[3, 22, 23] Ovulation was suppressed in our preliminary clinical trials even at a daily dose of 10 mg (unpublished data). The dose of 1 mg used in the current study did not consistently preserve ovulation while inhibiting endometrial development, as one woman was anovulatory and three had normal endometrial histology. These results suggest that this dose was too high in the first and too low in the latter cases. These differences in dose-response may reflect individual variations in absorption or metabolism of RU 486 and indicate that further work, including serum measurements of this compound, will be needed to define an optimal dose of the drug for contraceptive trials.

No adverse effects were observed during RU 486 treatment, suggesting that it can be safely administered in the regimen used in the current study. The subsequent menses were shortened, however, most likely due to RU 486 inhibition of endometrial development. The post–RU 486 cycle was ovulatory but slightly shortened. The mechanism by which this occurred was not apparent from the available data.

In summary, at a daily dose of 1 mg, RU 486 disrupted both the morphology and function of the endometrium while preserving steroidogenesis, ovulation, and timing of the cycle. Taken with our previous findings that daily administration of RU 486 prevents pregnancy in the guinea pig,[5] it is tempting to speculate that daily administration of an antinidatory dose of a progesterone antagonist may offer a novel strategy for fertility control. Although the dose used in women (0.016 mg/kg/day) was proportionally lower than in guinea pigs (1 to 3 mg/kg/day), this comparison may not be valid because of interspecies differences. Because our study group was small, the present data must be regarded as preliminary. However, this study demonstrates that, in principle, a small daily dose of an antiprogestational agent can inhibit both morphologic and functional maturation of the endometrium and thus provides a rationale for further investigations to elucidate the contraceptive potential of these agents in women.

We thank the nursing staff of the Ninth Floor Clinic of the Clinical Center of the National Institutes of Health and Ms. Barbara Filmore for supporting this study. We also thank Roussel-UCLAF for providing RU 486.

Antenatal tests of fetal welfare and development at age 2 years

Angela L. Todd, BA,[a] Brian J. Trudinger, MD,[a] Michael J. Cole, MB,[b] and George H. Cooney, PhD[c]

Westmead, New South Wales, Australia

OBJECTIVE: Our objective was to examine the outcomes at 2 years of age of fetuses delivered electively before 34 weeks, studied antenatally with two tests of fetal well-being.

STUDY DESIGN: Forty-two fetuses from high-risk pregnancies delivered electively by cesarean section before 34 weeks were stratified into normal versus abnormal subgroups with umbilical Doppler flow velocity waveform and fetal heart rate results. Developmental outcome was assessed at 2 years. Two comparison groups were also selected: 40 matched premature controls delivered spontaneously before 34 weeks and 67 normal babies delivered spontaneously at term. Frequency outcome data were tested with χ^2 analyses and the remainder with analyses of variance.

RESULTS: Within the electively delivered study group poor cognitive progress at 2 years was more strongly associated with an abnormal fetal heart rate result than an abnormal Doppler result. Compared with the premature control and normal term groups, electively delivered fetuses were significantly delayed in growth, cognition, and motor development ($p < 0.005$).

CONCLUSIONS: Adverse fetal welfare in a high-risk obstetric sample was associated with poorer outcome at 2 years. However, the whole of the group of fetuses from such high-risk pregnancies showed significant developmental delay compared with normal term children and, more importantly, matched premature infants delivered spontaneously from otherwise uncomplicated pregnancies. (Am J Obstet Gynecol 1992;167:66-71.)

Key words: Fetal compromise, high-risk pregnancy, Doppler, fetal heart rate, early childhood development

It is a goal of obstetrics to ensure that a fetus is born well and, through growth and development after birth, able to attain its full biologic potential. Antenatal tests of fetal well-being exist as aids to the obstetrician to determine the appropriate time for intervention and delivery. Clinical suspicion of fetal compromise is usually followed by ultrasonographic assessment of size and biophysical profile. Nonstressed fetal heart rate (FHR) monitoring has become the most widely used test of fetal condition and need for delivery. A normal tracing encourages the obstetrician to maintain the fetus in utero to gain maximal maturity. A persistent nonreactive tracing indicates encroachment on critical fetal reserve and the time for intervention. More recently, Doppler studies of the umbilical artery flow velocity waveform have been introduced.[1] Such studies identify a vascular pathologic condition in the fetal placenta.[2] Their use is based on the premise that this lesion precedes fetal effect and identifies pregnancies for intensive fetal surveillance.

There is increasing awareness that long-term developmental handicaps may originate from fetal insult during the antenatal period rather than during labor.[3, 4] Many descriptive studies have examined the relationship between tests of fetal well-being and condition at birth. However, there has been very little information relating fetal welfare test results with later infant and child development. In the current study we have investigated development at 2 years of age in a group of fetuses born after complicated pregnancies in whom Doppler umbilical flow studies and nonstressed FHR monitoring were conducted.

Patients and methods

Patients. The study group comprised children who had been delivered electively (by cesarean section) from high-risk pregnancies before or at 34 weeks' gestation. All had been assessed with Doppler flow velocity waveform studies within 2 weeks of delivery and FHR mon-

itoring within 3 days of delivery. They were all delivered at Westmead Hospital between 1986 and 1988 and had been identified for follow-up during pregnancy. This study was approved by the Research and Ethics Committee of Westmead Hospital.

At the 2-year follow-up 78 eligible subjects were contacted by mail and invited to participate. Forty-two subjects agreed to participate, 14 refused, and no contact was made with 22 subjects. There were no significant differences between participants and nonparticipants in gestation, sex, birth weight, antenatal test results, maternal age, or hospital health insurance status (used here as a broad indicator of social class) ($p > 0.05$). Clinical details of the 42 subjects in the study group are displayed in Table I. Gestation was determined by patient dates and, in 31 cases, confirmed by an ultrasonographic scan before 22 weeks. The major reasons for elective delivery were suspected or known fetal compromise ($n = 26$) and maternal hypertension ($n = 15$). In one case antepartum hemorrhage associated with placenta previa was the reason.

The antenatal results of the placental Doppler umbilical flow velocity waveform studies and FHR monitoring were used to divide the study group into normal and abnormal groups. The Doppler umbilical artery flow velocity waveforms were recorded as previously reported.[5] The systolic diastolic ratio was used as an index of downstream resistance. This result was classed as abnormal if it was above our 99.95th percentile.[6] This division was chosen as the statistical cut-off equivalent to absent diastolic flow in fetuses of 28 to 32 weeks' gestation. The nonstressed FHR trace was recorded at a paper speed of 3 cm/min. The abnormal FHR group included those fetuses with a nonreactive trace, defined by an FHR baseline variability <5 beats/min and no accelerations with or without late decelerations in response to Braxton Hicks contractions.[7] This stratification of the 42 children resulted in 17 normal and 25 abnormal Doppler study cases and 26 normal and 16 abnormal FHR cases. The correlation between Doppler study and FHR result was $r = 0.25$ ($p = 0.057$).

For comparison two further groups were selected for study. A control group delivering before 34 weeks after spontaneous onset of labor was chosen. This group ($n = 40$) was matched to the electively delivered study group for gestation (±1 week) and health insurance status. All children had birth weights >5th percentile and Apgar scores at 1 and 5 minutes of ≥5 and 7, respectively. A group of fetuses delivered spontaneously at term (37 to 42 weeks' gestation) was also selected to provide a normative range. In this group (67 patients) all birth weights were >5th percentile, and Apgar scores at 1 and 5 minutes were ≥7 and 9, respectively. Complete antenatal testing was not available for the premature control and term groups, but case selection ensured there was no history of obstetric complications or evidence of fetal compromise during pregnancy.

Table I. Clinical details of electively delivered pre-34-week study group

Cases (No.)	42

Boys (No.)	14 (33%)
Mother's age (yr, mean ± SD)	26.4 ± 5.5
Nulliparous (%)	57
Private health insurance (%)	60

Methods. Children were reviewed at 2 years of age, corrected for gestation, and assessed for physical, cognitive, and language outcome. Mean corrected age at time of assessment was 24.9 months, with a range of 21 to 30 months.

Weight, height, and head circumference measurements were recorded and percentiles calculated.[8, 9]

The Denver Developmental Screening Test[10] was administered. This test is designed to screen children for risk of delay in personal-social, fine motor, gross motor, and language development. The scoring of this test was modified so that the number of failures and the areas in which they occurred were recorded.

The Bayley Scales of Infant Development[11] were used to assess the achievement of milestones at 2 years. The test provides a Mental Development Index incorporating fine motor skills, eye-hand coordination, and some language items, and a Psychomotor Development Index examining coordination and balance of the larger leg muscles.

Language progress was tested with the Sequenced Inventory of Communication Development.[12] The test comprises two scores: a receptive score relating to the child's understanding of language and an expressive score reflecting the child's ability to produce sounds and words.

In addition, parents supplied demographic details such as level of schooling and occupation to index social class.[13] Information on the home environment was obtained with three subtests from Caldwell's HOME scale,[14] labeled maternal responsivity, maternal involvement, and provision of toys and play materials. These subtests were selected because of the strong correlations reported with early development.[15, 16]

Statistics. Data were corrected for gestation where appropriate. In all comparisons the eight outcome mea-

sures at 2 years corrected age were weight; height; head circumference; number of items failed on the Denver Developmental Screening Test, Bayley Mental Development Index, and Psychomotor Development Index, and receptive and expressive Sequenced Inventory of Communication Development language scores. Frequency data (Denver Developmental Screening Test score, Sequenced Inventory of Communication Development scores) were tested with χ^2 analyses. The remaining data (growth parameters, Bayley Mental Development Index and Psychomotor Development Index) were analyzed with analyses of variance, which included sex, social class, and the HOME total score as covariates. It is well established that these three factors relate to child development, and using covariate analysis was intended to increase the power of the statistical test by reducing the error variance.

Data were tested in two stages. To examine the value of the two antenatal tests the outcome data within the electively delivered study group were analyzed comparing the normal and abnormal groups for each fetal test. The effect of the other antenatal test result was controlled in the analyses of variance with covariate analysis. This ensured that any significant differences were not confounded by the other antenatal test result.

Comparisons were then made between the elective study group and the premature control and the normal term infants. The developmental status of the study group relative to the control groups was also analyzed with both antenatal test divisions. A p value of 0.005 was considered significant to minimize type I errors. Significant differences were tested with post hoc, pairwise χ^2 tests or Tukey tests on adjusted means, with a significance level of $p < 0.01$ to correct for multiple comparisons.

Results

Differences within the study group. Outcome data within the electively delivered group stratified by Doppler and FHR results are displayed in Table II. Stratification by the Doppler umbilical fetal velocity waveform result revealed no significant differences ($p > 0.05$). Comparison of the FHR results showed a significant difference on the Bayley Mental Development Index ($p < 0.05$). Trends were apparent on the Bayley Psychomotor Development Index ($p = 0.07$) and Denver Developmental Screening Test ($p = 0.09$). An analysis of the subgroup in whom both the Doppler and FHR results were abnormal showed trends similar to the abnormal FHR group, particularly on the Bayley tests (Mental Development Index $p = 0.13$, Psychomotor Development Index $p = 0.04$).

Although the purpose of the study was the investigation of antenatal well-being and outcome at 2 years we also examined several neonatal measures from the newborn period, for possible confounding effects. Comparisons of the study group stratified by either Doppler or FHR result revealed no significant differences between the normal versus abnormal groups on the following variables: total days in neonatal intensive care, total time on oxygen, incidence of necrotizing entercolitis, or incidence of cerebroventricular hemorrhage.

Differences between the study group and control groups. Table III displays the outcome data of the electively delivered study group and the two control

groups. Post hoc analyses showed the electively delivered study children were significantly smaller than term babies in both weight and height ($p < 0.01$). Babies in the premature control group were also shorter than term babies ($p < 0.01$). On both Bayley indexes the study group scored significantly below both control groups ($p < 0.01$).

The study group was divided by the results of the umbilical Doppler and FHR tests and compared with the control groups, with the data displayed in Tables II and III. Analyses indicated the electively delivered study children in whom the Doppler results were abnormal performed significantly below the normal term group in all growth parameters and both Bayley indexes ($p < 0.01$). The abnormal Doppler group also differed from the premature control group on the Bayley Psychomotor Development Index ($p < 0.01$). In the subgroup with a normal Doppler result developmental scores were consistently lower, but none of these differences were significant.

Using the FHR test division both the abnormal and normal study children had lower weight and height at 2 years compared with children delivering at term ($p < 0.01$). The abnormal FHR group scored significantly below both control groups on the Bayley indexes ($p < 0.01$). More children in the abnormal FHR group failed at least one item (31%) on the Denver Developmental Screening Test compared with both the premature (5%) and the term (3%) control groups ($p < 0.01$). Analysis of variance results of the receptive language scores on the Sequenced Inventory of Communication Development were significant ($p < 0.005$), but post hoc tests did not detect a pairwise difference at $p < 0.01$. Differences existed between the normal FHR study group and controls on the Denver Developmental Screening Test and Bayley tests but did not reach significance.

Comment

This study was designed to evaluate growth and development of children at 2 years of age against the results of fetal welfare tests carried out during pregnancy in a high-risk obstetric population. It was expected that children with abnormal fetal welfare test results would fare worse than those with normal results. We found that fetuses delivered electively before 34 weeks did show some differences at 2 years when divided by the result of antenatal tests of fetal well-being. The subgroup with an abnormal result was developmentally behind the normal subgroup in many areas, but few differences reached statistical significance. We found the result of FHR monitoring rather than umbilical Doppler study was a better discriminator of developmental progress at 2 years. Umbilical Doppler studies are an early detector of placental vascular pathologic conditions, which are believed to lead to fetal constraint. An abnormal result in this test will include cases in which the fetus has been affected and others in which this has not yet occurred. It is therefore not surprising that the difference between the normal and abnormal Doppler subgroups is small. In contrast, an abnormal FHR result indicates that a fetal effect has

occurred. The differences found between the normal and abnormal FHR subgroups support this point.

On the basis of results within our study group showing only a small difference in outcome for infants with an abnormal versus normal antenatal test, it could be concluded that, in spite of an adverse antenatal environment, timely delivery aided by the results of fetal welfare tests has allowed the fetus to emerge relatively unscathed. However, we have shown that, as a group, children from complicated pregnancies delivered electively before 34 weeks performed markedly below peers selected from uncomplicated normal term pregnancies. This is consistent with previous studies.[17, 18] More importantly, the electively delivered children also exhibited delays compared with a matched preterm group who had delivered spontaneously before 34 weeks. The children delivered electively from high-risk pregnancies showed poorer performance at 2 years in physical growth, cognition, and motor performance when compared to both control groups. Further analyses indicated that in particular children with an abnormal antenatal test result, whether Doppler or FHR, were indeed exhibiting the most developmental deficits. However, the study children in whom the fetal welfare test results were normal were also consistently behind their peers in the control groups, although not always reaching statistical criteria. Although the number of cases in the subgroups are small, the differences between the elective study group as a whole and the control groups are highly significant.

In this study we assessed only 54% of the electively delivered infants identified for follow-up from the antenatal period. We have compared participants and nonparticipants on gestation, sex, birth weight, antenatal test results, maternal age, and hospital health insurance status and found no differences. The possibility of bias, however, is not excluded. Among our control groups we do not have details of Doppler and FHR results. These pregnancies were uncomplicated, and there was no reason for these tests to be performed. Our control groups may have included some cases of unrecognized fetal compromise, but the effect of this would have been to reduce the differences between the groups. Our findings may in fact underestimate the true disparity.

The poor overall performance of our study group at 2 years raises questions about the timing of fetal injury and the feasibility of preventing it by early intervention (delivery). There is no doubt nonstressed FHR monitoring facilitates delivery of a fetus in the best possible condition at birth. This short-term role should not be undervalued. Our data would question the long-term benefits of this course of management in ensuring normal developmental outcome. Clearly there exists scope for the pursuit of other avenues of fetal surveillance and management if obstetric intervention is to be timed to precede fetal damage. It may be that fetal injury is a cumulative result of adverse circumstances operating since early in the pregnancy and therefore not totally preventable by current obstetric practice. It is likely the same considerations are relevant when considering major handicaps, such as cerebral palsy, originating from antenatal insult.

In addition to the effects of fetal well-being the importance of the early social and emotional environment of the child must be considered. Perinatal complications have been found to be associated with poorer physical and psychologic development only when combined with a persistently poor environment.[18-20] Given the potential palliative role of the child's early postnatal environment, it appears that evaluation of targeted remedial parenting programs for infants delivered electively before term is also warranted. This represents a new and important approach to therapy.

In summary, we have shown in this study that in the presence of potential fetal compromise delivery before the development of a nonreactive FHR tracing is associated with a better outcome in terms of growth and development at the age of 2 years. However, it does appear that such pregnancies yield fetuses who, as a group, exhibit suboptimal early childhood development. By the time the signs of fetal compromise are present fetal damage has already occurred. This points to the need for new approaches in management.

Retrospective maternal mortality case ascertainment in West Virgina, 1985 to 1989

Timothy D. Dye, MA, MPA, MS,[a, c] Howard Gordon, MD,[d] Berel Held, MD,[b, e] Nancy J. Tolliver, MSIR,[b] and Alan P. Holmes, MBA[a]

Charleston, Morgantown, and Huntington, West Virginia

OBJECTIVE: The death of women from pregnancy-related causes remains a threat to national maternal and child health. Maternal deaths as persistent, albeit rare occurrences are overlooked if vital registration systems are relied on to report such deaths.

STUDY DESIGN: Live birth records were matched with death records for women of reproductive age to detect if a woman died within 1 year of delivery. The data for potential cases were reviewed by committee and classified as maternal and nonmaternal deaths.

RESULTS: Of all linked birth-death records, 32% were related to pregnancy: 81% were directly related to pregnancy and 19% were indirectly related to pregnancy. The most frequent causes of death were hemorrhage and embolism. Thirty-eight percent of the women were transferred to tertiary hospitals before death. The case ascertainment through this study improved maternal death detection by 100% over official vital statistics.

CONCLUSION: Enhanced maternal mortality surveillance increased the detection of maternal death in West Virginia. Case review of these deaths yielded important information useful in shaping the state's perinatal system. (AM J OBSTET GYNECOL 1992;167:72-6.)

Key words: Maternal mortality, vital registration, mortality review, record linkage, West Virginia

The death of women from causes related directly or indirectly to pregnancy and childbearing remains a persistent threat to maternal and child health not only in developing countries[1] but also in the United States.[2] The existence of state and locally based maternal mortality review committees (e.g., North Carolina,[3, 4] Iowa,[5] Oklahoma,[6] and Massachusetts[7]) have enabled long-term analysis of trends in maternal death. In addition, the establishment of the Maternal Mortality Collaborative of the American College of Obstetricians and Gynecologists has enabled improved surveillance of maternal mortality in selected areas of the United States.[2] In states where maternal mortality review committees do not currently exist, for example, West Virginia, the existence of maternal death as an important and persistent, albeit relatively rare, occurrence may be overlooked if traditional vital registration systems are relied on as the only sources of reporting such deaths. Death certificate information available through traditional vital registration systems are not adequate for enhanced detection of maternal deaths, the American College of Obstetricians and Gynecologists Maternal Mortality Collaborative found that maternal death was underreported by vital registration in selected areas of the United States by 39% during 1980 through 1985.[2] In particular, in West Virginia, where the provision and organization of obstetric and medical care has reached crisis proportions in recent years,[8] enhanced maternal mortality surveillance is an important activity in assessing the current status of maternal and child health.

Material and methods

Record linkage and data sources. According to the methods of other similar studies of maternal death,[9, 10] we matched all deaths among West Virginia resident women aged 10 to 49 years (n = 2623) and out-of-state resident women dying in West Virginia (n = 351) between 1985 and 1989 against all live births to West Virginia residents (n = 138,178) and out-of-state residents (n = 17,454) between 1984 and 1989. Seven maternal deaths were reported through the state's vital registration system for this period; all seven deaths were also identified through the linkage procedure. The woman's death certificate was matched with the baby's birth certificate if the woman died within 1 year of the birth. The record match was based on social

security number, mother and baby's name, and mother's date of birth. All matches were hand-verified to assure correct linking of the mother-infant pair. This record linkage yielded a cohort of women dying within 1 year after giving birth ($n = 49$). Additionally, all women with causes of death from *International Classification of Diseases, Ninth Revision* Codes 630 through 679 (Complications of Pregnancy, Childbirth, and Puerperium), who were not identified by the record linkage ($n = 1$) were added to the linked records to be reviewed. Because of a lack of unique case-identifying information, record matches with other pregnancy outcome records (i.e., abortion records, fetal death records) were not possible for the time of this study. The final set of matched-identified potential maternal death cases ($n = 50$) represents all women dying within 1 year after giving birth, including women previously identified through vital registration as dying of maternal causes regardless of termination status (e.g., ectopic pregnancy). Data assembled for all potential maternal death cases ($n = 50$) included the woman's death certificate and baby's birth certificate (certificate not available for one ruptured tubal pregnancy). Medical records for the woman and the baby, including autopsy reports, were requested for all women dying of non-injury-related causes ($n = 28$). Hospital and medical records were obtained for the woman ($n = 27$) and the baby ($n = 24$), and autopsy reports were obtained for 12 women (of 15 autopsies conducted).

Obstetric review. The data assembled for all potential maternal death cases ($n = 50$) were reviewed by two in-state and two out-of-state obstetricians. The protocol was approved by the West Virginia University Institutional Review Board.

The purpose of the maternal death review team was to categorize each case as a maternal or nonmaternal death. Maternal deaths were further defined as direct maternal deaths or indirect maternal deaths. Operational definitions of maternal death, direct maternal death, indirect maternal death, and nonmaternal death, on the basis of definitions used by the Maternal Mortality Collaborative[2] and the Massachusetts Medical Society's Committee on Maternal Welfare,[11] as applied in this study were as follows:

Maternal death. A maternal death is a death caused or contributed to by pregnancy occurring during pregnancy or within 1 year after the end of pregnancy.

Direct maternal death. A direct maternal death is a death resulting from complications of pregnancy, labor, delivery, or their management. Also, a maternal death is one resulting from intervention elected or required by the pregnancy or resulting from the chain of events initiated or complicated by the intervention.

Indirect maternal death. An indirect maternal death is a death in which pregnancy exacerbated a preexisting health problem. Also, an indirect maternal death results from a disease developing before or during pregnancy that was aggravated by the physiologic effects of the pregnancy and caused death.

Nonmaternal death. A nonmaternal death is a death occurring during pregnancy or within 1 year of termination of pregnancy but considered unrelated to pregnancy, its complications, or management (e.g., accident, homicide, suicide).

The final case designations (direct maternal death, indirect maternal death, and nonmaternal death) were reached by consensus among the obstetric reviewers.

Analysis. To quantify the magnitude of maternal death in West Virginia, crude maternal mortality ratios are presented for each year of the study period (1985 through 1989). Maternal mortality ratios were calculated as the number of maternal deaths during a specified period ($\times 100{,}000$) divided by the total number of live births during the same period.[12] The resulting ratio reflects the number of women dying of maternal causes per 100,000 live births. Because mode of delivery information was collected only for 1989, maternal mortality rates specific to vaginal and cesarean deliveries could not be computed. To describe the circumstances and characteristics of maternal death in West Virginia, basic frequency distributions are presented for demographic characteristics and delivery characteristics of all maternal deaths.

Results

Forty-nine women dying within 1 year after giving birth were identified by the record linkage procedures and were subsequently reviewed as potential maternal deaths (Fig. 1). In addition, one woman whose death resulted from a ruptured ectopic pregnancy that did not terminate in a live birth was identified through vital registration coding.

Of these 50 deaths reviewed, 16 (32%) were determined to be directly or indirectly related to the woman's pregnancy, its management, or complications. Thirteen of these maternal deaths (81%) were determined to be directly related to the pregnancy, whereas three deaths (19%) were indirectly related to the pregnancy. Thirty-three cases (66%) were determined unrelated to the woman's pregnancy: 22 cases (67%) were attributable to injuries (including accidents, homicide, and suicide) and 11 cases (33%) were attributable to non-injury-related causes. Insufficient information was available for one case; therefore a definitive designation could not be assigned.

Overall, the maternal mortality ratio for the 1985 through 1989 study period, or the risk of death from maternal causes among women giving birth during this

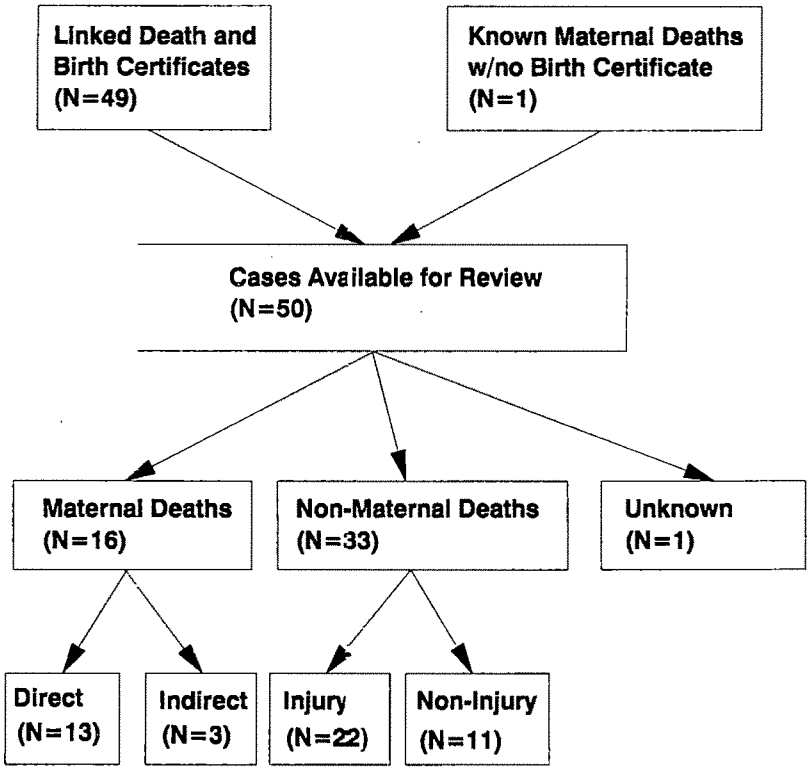

Fig. 1. Disposition of potential cases, maternal mortality study, West Virginia, 1985 through 1989.

period, was 12.4 maternal deaths per 100,000 live births (Fig. 2). The ratio increased from 3.8 and 3.9 in 1986 and 1987 (respectively) to 12.1 in 1988 and 31.9 in 1989. The actual number of maternal deaths identified between 1985 and 1988 (eight deaths) equaled the number of deaths identified from 1989 alone.

All women dying of maternally related causes between 1985 and 1989 were <40 years old (Table I), with one death (6%) in a woman <20 years old, 10 deaths (63%) in women between 20 and 29, and five deaths (31%) in women between 30 and 39. Fourteen white women (88%) and two black women (13%) died of maternal causes during the study period. Eleven maternal deaths (69%) were in women residing in rural, non–Standard Metropolitan Statistical Areas. As shown in Table I risk of maternal death was higher among black women and among older (≥30) women.

All women died within 90 days of giving birth: 10 women (63%) died within 7 days of delivery, three additional women (19%) died between 8 and 30 days of delivery, one woman (6%) died between 31 and 42 days of delivery, and two women (13%) died between 43 and 90 days of delivery. Nine women (56%) gave birth in non–level III hospitals, and seven women (44%) died in non–level III hospitals. Six women (38%) were transferred to level III hospitals either before (two women) or after delivery (four women). The primary mode of delivery for women dying of maternal causes in this study was cesarean section (69%), with seven emergency and four planned cesarean sections indicated in the records. Half of the women (50%) were delivered at term.

The most frequent immediate causes of maternal death were hemorrhage (25%) and embolism (19%). Two women each died of cardiomyopathy and hypertensive disease, and one woman each died of infection and complications of anesthesia. Three women (19%) died of other indirect causes. In addition, four maternal deaths (25%) were complicated by preeclampsia, four deaths (25%) were complicated by respiratory problems, and three deaths were complicated by anesthesia. Motor vehicle accidents contributed to 15 nonmaternal deaths (45%), with cancer contributing to five nonmaternal deaths (15%), suicide contributing to four nonmaternal deaths (12%), and homicide contributing to three nonmaternal deaths (9%).

Finally, the woman's recent pregnancy status was mentioned in the medical records of all 16 maternal deaths. The death certificates of 11 maternal deaths mentioned or referred to the woman's recent pregnancy, and seven maternal deaths were coded and reported previously from the death certificates as maternal deaths.

Comment

The magnitude of maternal mortality in West Virginia during the period of 1985 to 1989 is difficult to

interpret in a national context; annual maternal mortality ratios published by the National Center for Health Statistics are based on vital registration information alone, which has been shown to underreport maternal death. The national maternal mortality ratio of 8.0 maternal deaths per 100,000 live births for 1988, the highest national ratio since 1983,[13] while most likely underreporting true maternal mortality still indicates a slight increase in maternal mortality over 1987 (6.1 maternal deaths per 100,000 live births). Importantly, West Virginia's maternal mortality ratio increased in the last 2 years (1988 and 1989) of the study period, essentially reflecting this increaase in maternal mortality nationwide. Furthermore, substantial effort must be devoted to reducing maternal mortality in West Virginia in concordance with the year 2000 goal of no more than 3.3 maternal deaths per 100,000 live births.[14]

The major causes of maternal death in West Virginia (hemorrhage, embolism, hypertensive disease) reflect national findings.[2] This study, however, most likely underestimates true maternal mortality in West Virginia because the method used will not detect deaths attributed to maternal causes, either directly or indirectly, unless (1) the pregnancy resulted in a live birth or (2)

pregnancy status was noted on the woman's death certificate and the certificate was coded and reported as a maternal death. Information collected nationally indicates that approximately 52% of all maternal deaths are to women whose pregnancy resulted in a live birth.[15] Additionally, some nonmaternal deaths (e.g., suicide, accidents) may indeed be maternally related although not through the readily identifiable medical information available to reviewers. For these reasons the findings of this study may underreport true maternal mortality in West Virginia if such mortality includes deaths to women whose pregnancies did not terminate with a live birth or if the cause of death appeared to be nonmaternal (e.g., suicide).

The review committee approach to identifying maternal deaths for the study period enhanced the state's detection of reproduction-related deaths. Although vague or absent legal protection of findings from such review groups and, indeed, participation on such review groups threatens maternal mortality review throughout the United States,[16] West Virginia's *Code* explicitly provides immunity from liability for the review group and protects the group's findings from being subject to subpoena or discovery.[17] Importantly, the case ascertainment achieved through this study design improved maternal death detection in West Virginia by 100% over traditional vital statistics mechanisms. The woman's pregnancy status was mentioned in the medical records of all maternal deaths; however, only seven maternal deaths were officially reported by vital statistics. The failure to detect five of these maternal deaths was due to pregnancy status being missing from the death certificate. An additional four maternal deaths with pregnancy status indicated on the death certificate were not coded and reported as maternal deaths. Clearly, improvements in the recording and coding of maternal cause of death could improve traditional vital statistics systems capabilities substantially in the detection of maternal death.

We thank the medical records departments of all involved hospitals and the Office of Chief Medical Examiner for assistance and cooperation in releasing medical records information and autopsy reports. We also thank Joe Kennedy, Tom Leonard, Gary Thompson, and Tom Light of the West Virginia Health Statistics Center for their technical assistance in conducting the computer linkages for this research and Jack Smith and Lisa Koonin from the Division of Reproductive Health at the Centers for Disease Control for their assistance during this project. Finally, we thank the anonymous in-state and out-of-state physicians who served as case reviewers for this project.

Laparoscopic diagnosis and repair of spigelian hernia: Report of a case and technique

James E. Carter, MD, PhD, and Craig Mizes, MD
Mission Viejo, California

Spigelian hernia is an uncommon hernia of the abdominal wall. We report a case of acquired spigelian hernia diagnosed and treated by laparoscopy. With more extensive use of laparoscopy to evaluate abdominal pain, the diagnosis of spigelian hernia can be made and repair accomplished without need for open exploratory surgery. (Am J Obstet Gynecol 1992;167:77-8.)

Key words: Spigelian hernia, laparoscopy, abdominal wall defect

Spigelian hernia is an uncommon defect of the abdominal wall. Bogojavlensky introduced laparoscopic treatment of inguinal and femoral hernias by preperitoneal patch repair at the 1989 meeting of the American Association of Gynecological Laparoscopists. In 1990 Popp[1] published a case of endoscopic patch repair in a female patient. We report the first case of spigelian hernia diagnosed and treated by laparoscopic techniques.

Case report

A 72-year-old woman was evaluated for a complaint of splitting lower abdominal pain of many years' duration, which had become progressively worse. She first noticed the pain about 6 months after abdominal hysterectomy performed in 1968 through a midline incision. In 1967 she had a tubal ligation through a minilaparotomy Pfannenstiel incision.

Physical examination outlined an area of tenderness along the left side of the abdominal wall. No fascial defect was felt. A small umbilical hernia was noted, which the patient stated was there from birth. A computed tomographic scan revealed a liver abnormality for which a liver biopsy was recommended.

Diagnostic approach. We performed laparoscopy to determine the source of the pain and to evaluate and perform a biopsy of the liver. The midclavicular line 2 cm below the right lowest rib margin was chosen as the puncture site for the 5 mm diagnostic laparoscope. This provided access to the liver for biopsy and for a full view of the umbilical hernia and lower pelvis.

The umbilical view revealed a 3 × 4 cm umbilical hernia defect with no adhesions. The infraumbilical region revealed a large omental adhesion herniating into a 10 cm defect in the semilunar line. The laparoscope was inserted into the gaping hernia. Palpation of the abdominal wall above the defect confirmed that the anterior abdominal wall was intact.

Surgical approach. Laparoscopic repair of the spigelian hernia required port sites for instrument insertion, which allowed triangulation and laparoscopic suturing of the defect: the midclavicular line 3 cm below the costal margin, 4 cm above the umbilicus in the midline, and 5 cm lateral to the umbilicus at that level.

The herniated omental tissues were bluntly and sharply dissected from within the defect. Bleeding was controlled with bipolar coagulation at 40 W. Once the defect was free of its omental contents, the abdominal wall was carefully inspected. No defect of the wall itself was visualized.

Repair of the hernia was then accomplished by laparoscopic placement of No. 1 Vicryl sutures on a CT 2 needle in an interrupted-Figure-eight pattern. Ten sutures effected complete closure. Ties were accomplished with the extracorporeal knotting procedure of Semm[2] with the Marlow knot pusher. The 45-degree, 5 mm Cook Ob/Gyn endoscopic needle driver (Kenh-053130) facilitated suturing on the anterior abdominal wall. The umbilical hernia was closed in a similar fashion.

Laparoscopic suturing on the anterior abdomen was facilitated by: (1) placement of suture and camera ports on the far contralateral side from the defect so the opposite anterior wall could be viewed and the needle delivered to the suturing site; (2) establishment and maintenance of 15 mm Hg pneumoperitoneum to assure a dome-shaped abdominal cavity; (3) external manipulation of the abdominal wall to bring both sides of the defect into full view; (4) use of the 45-degree-angle Cook needle driver to facilitate reverse acute-angle suturing; (5) suture lubrication to facilitate sliding each throw of the knot.

Comment

The hernia described by Andrian van der Spieghel (1578-1625) is one of the less common anterior abdominal wall hernias. The spigelian hernia occurs through congenital or acquired defects in the spigelian fascia of the transverse abdominis aponeurosis lying between the semilunar line and lateral edge of the rectus muscle. In 1764 Klinklosch named it *Spieghel's linear hernia.* Spangen detailed its anatomic aspects in 1976. In 1984 Spangen reviewed the published material on spigelian hernias and found that 744 patients had required surgery. No reports of laparoscopic repair have been made.

Many reports of spigelian hernia emphasize the difficulty in making the diagnosis. The nonspecific symptoms and intramural location are contributing factors.

Although uncommon, spigelian hernias are a source of abdominal pain. Many require emergency surgery. Laparoscopic evaluation of abdominal pain can allow diagnosis before laparotomy. With the technique described here spigelian hernias can be repaired laparoscopically and open exploratory surgery can be avoided.

Oligohydramnios and megacolon in a fetus with vesicorectal fistula and anal-urethral atresia: A case report

Mordechai Hallak, MD,[a] Alexander A. Reiter, MD,[a] Leon G. Smith, Jr., MD,[a] Gary A. Dildy III, MD,[a] and Milton J. Finegold, MD[b]

Houston, Texas

Severe oligohydramnios and extremely dilated bowel filled with hyperechogenic material floating in fluid were the ultrasonographic findings in a fetus at 27 weeks' gestation. Vesicorectal communication and urethral-anal atresia permitted urine to empty into the colon, causing megacolon, oligohydramnios, and markedly increased intraabdominal pressure resulting in pulmonary hypoplasia. (AM J OBSTET GYNECOL 1992;167:79-81.)

Key words: Oligohydramnios, fetal vesicorectal fistula, fetal megacolon, pulmonary hypoplasia

Malformations of the urogenital sinus are often associated with oligohydramnios and cystic dilatation of various segments of the urinary tract.

We present the first case to our knowledge that describes the prenatal ultrasonographic findings of a fetus with anal-urethral obstruction and spontaneous decompression of the urinary tract into the colon through a vesicorectal fistula. Autopsy findings were helpful in making the clinical-pathophysiologic correlations.

Case report

A 21-year-old primigravid woman was referred to our prenatal diagnostic center at 27 weeks' gestation because of severe oligohydramnios. She was exposed to parvovirus B-19 during the first trimester of her pregnancy. No rash or fever was noted, yet laboratory tests showed elevated maternal serum parvovirus B-19 IgG antibodies and low levels of immunoglobulin M, consistent with recent exposure or infection.

The ultrasonographic examination showed severe oligohydramnios, elevated diaphragms, compressed chest, and markedly distended abdomen and bowel. The abdominal cavity was completely occupied by a large cystic structure containing fluid and hyperechogenic substance (Fig. 1). Peristalsis-like waves were noted to be present within the mass. Kidneys and bladder appeared normal, and no other abnormalities were identified. The differential diagnosis included the conditions that are known to cause fetal intraabdominal calcifications. Meconium peritonitis was the leading consideration, although the floating nature of the hyperechogenic material was atypical. Other possibilities were tumors (hemangioma, hemangioendothelioma, hepatoblastoma, teratoma, and metastatic neuroblas-

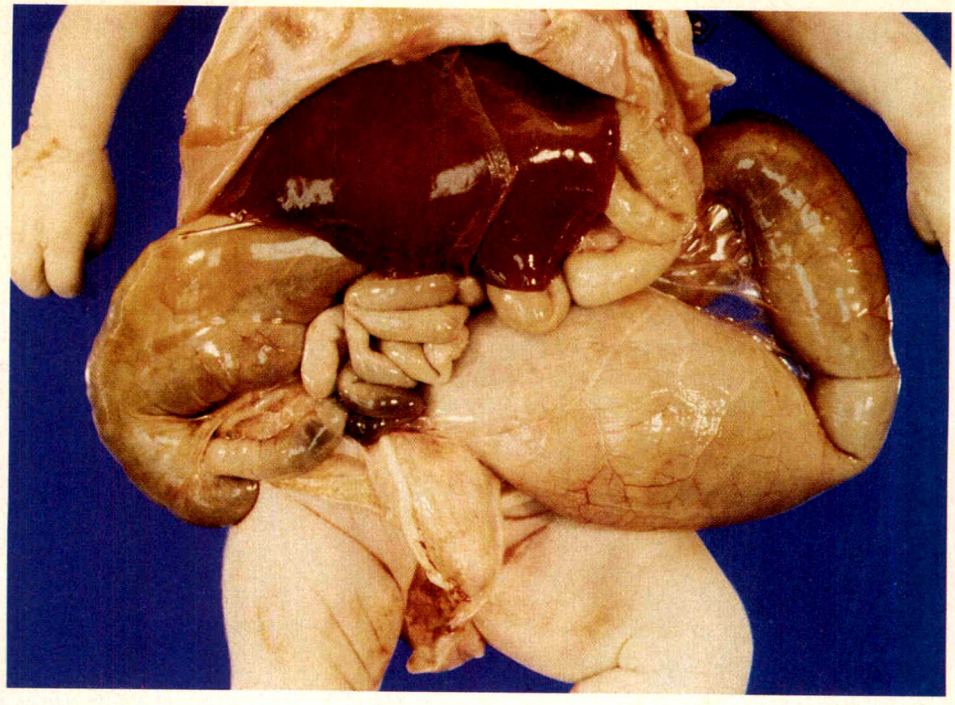

Fig. 2. Autopsy findings of extremely distended colon in association with urethral obstruction and vesicorectal fistula.

toma) and congenital infection (toxoplasmosis, cytomegalovirus). In an attempt to establish the diagnosis the patient was offered amniocentesis and cordocentesis for karyotype determination, as well as culture and serologic testing for cytomegalovirus, toxoplasmosis, and parvovirus. It was also intended to evaluate intestinal isozymes of alkaline phosphatase in amniotic fluid, as well as to perform molecular genetics studies for diagnosis of cystic fibrosis. However, the patient declined any invasive diagnostic procedures.

Serial ultrasonographic examinations continued to show the large echogenic abdominal mass and severe oligohydramnios. At 36 weeks' gestation she was admitted to the hospital in active labor. A 2650 gm male infant was delivered by emergency cesarean section for fetal distress. Apgar scores were 1 and 3 at 1 and 5 minutes, respectively. The infant was noted to have Potter's facies, lower-extremity deformation, markedly distended abdomen, imperforate anus, and ambiguous genitalia. Soon after delivery the infant was intubated and ventilated for respiratory insufficiency. Resuscitation was pursued after an episode of cardiac arrest, but the infant eventually died 4 hours after birth.

The final pathologic diagnoses included pulmonary hypoplasia, most likely as a secondary effect of the extremely distended colon (Fig. 2) and oligohydramnios. The diaphragms were elevated to the level of the third rib bilaterally. The colon was filled with watery, flocculent, yellowish green material identified as a mixture of meconium and urine. A fistula was identified between the distal bladder–proximal urethra to the rectum, and anal-urethral atresia was noted. Normal kidneys and ureters, normal penis, and undescended left testes were seen. Neonatal blood revealed a normal 46,XY karyotype.

Comment

During embryogenesis the cloaca is normally divided by a sheet of mesenchyme, the urorectal septum, into the urogenital sinus anteriorly and the rectum and upper anal canal posteriorly.[1] This process is completed by 6 weeks' gestation. In some cases, like the one presented, incomplete separation of the cloaca by the urorectal septum occurs. This type of malformation consists of anorectal agenesis with a fistula to the proximal urethra in male fetuses or the vagina in female fetuses. The prevalence of congenital abnormalities of the anus and rectum in general is approximately 1 in 5000 newborns. However, the prevalence of anorectal agenesis is even less. The associated urethral atresia in this case is more unique. It caused a diversion of urine into the colon and led to lethal complications, such as oligohydramnios and hypoplastic lungs.

This case presented a diagnostic dilemma to the perinatologist and the pediatric surgeon. This entity should be added to the differential diagnosis of fetal

abdominal mass as seen by ultrasonography. The ultrasonographic findings were hyperechogenic material floating in an abdominal mass and severe oligohydramnios in the presence of normal-appearing kidneys, ureters, and bladder. Persistent vesicorectal communication with anal and urethral atresia permitted urine to empty into and distend the entire colon. The mixture of meconium and urine produced the ultrasonographic picture of hyperechogenic material floating in fluid. The diversion of urine protected the kidneys and ureters from obstructive dysplasia and hydronephrosis-hydroureter. However, severe oligohydramnios, elevated diaphragms, and thoracic compression probably led to pulmonary hypoplasia and neonatal death.

This malformation was considered a sporadic event not related to a genetic disorder, infectious etiology, or specific teratogens. There does not appear to be a temporal relationship between the documented maternal parvovirus infection and the malformation that led to lethal secondary consequences. There have been no reports of such an association.[2]

Prenatal recognition of this entity at an early stage might permit operative urinary diversion. In theory, urine diverted into the amniotic cavity could prevent oligohydramnios, bowel distention, or pulmonary hypoplasia.

Pathways to hysterectomy: Insights from longitudinal twin research

Susan A. Treloar, MSW,[a] Nicholas G. Martin, PhD,[a] Lorraine Dennerstein, PhD,[b] Beverley Raphael, MD,[c] and Andrew C. Heath, DPhil

Brisbane, Queensland, and Melbourne, Victoria, Australia

OBJECTIVE: We hypothesized that genetic influences act on "liability" to hysterectomy, that secular influences might differentially affect relative importance of genetic and environmental influences, and that the sources of genetic influences could be identified from reported risk factors.

STUDY DESIGN: Hysterectomy data from an Australia-wide volunteer sample of female adult monozygotic and dizygotic twins are reported. In 1980 through 1982 a mailed questionnaire was completed by 1232 monozygotic female twin pairs and 751 dizygotic female twin pairs (3966 women) from the Australian Twin Register (wave 1). The same twins were surveyed by questionnaire 8 years later (wave 2).

RESULTS: A total of 366 had undergone hysterectomy by wave 1 and a further 198 at wave 2. The twin-pair correlations for liability to hysterectomy at wave 1 (0.61 ± 0.06 for monozygotic and 0.20 ± 0.11 for dizygotic) and wave 2 (0.65 ± 0.05 for monozygotic and 0.32 ± 0.09 for monozygotic) indicated a substantial genetic contribution. Reported risk factors accounted for only 15% of total variance.

CONCLUSION: Genetic influences on liability to hysterectomy were substantial and stable across birth cohorts, but the important sources of genetic influence on liability to hysterectomy are yet to be identified.

(Am J Obstet Gynecol 1992;167:82-8.)

Key words: Hysterectomy, twins, genetic influences

Hysterectomy has been the subject of considerable recent investigation as a result of the need to distinguish "real" clinical indications for the procedure from service provision distortions arising from health financing systems. In Australia the incidence of hysterectomy peaked in 1978,[1] with an age-standardized rate of 460 per 10^5,[2] compared with the United States peak in 1975.[3] The 1973 rate in the United States was 651 per 10^5 women, still significantly higher than the age-standardized Australian rate, which had declined to 376 per 10^5 by 1983. There is less variation in rate between Australian states than within the United States.[2]

Investigation of patient characteristics has found variance to be associated with factors such as race, education, and parity.[4] The role of patient demand in influencing hysterectomy rates in Australia has been noted,[5] and high prehysterectomy levels of psychiatric symptoms have been reported.[6, 7] To investigate further the causes of hysterectomy in Australian women, this prospective two-wave study of twins sought to identify the relative roles of environmental and genetic factors on "liability" to hysterectomy and the extent to which these are modulated through known risk factors. Twins discordant for hysterectomy, particulary monozygotic pairs, offer the ultimate matched-pair design to detect the effect of independent variables measured before the operation, and we have taken advantage of the 106 discordant pairs in our study for this purpose. We also investigated whether genetic effects could be detected on the age at which hysterectomy was performed in pairs concordant for hysterectomy.

Methods

Wave 1 (1980 through 1982). In 1980 through 1982, as part of a health survey by mailed questionnaire, information about hysterectomy was obtained from 1983 female twin pairs in a large sample of 3808 adult twin pairs from the Australian National Health and Medical Research Council Twin Register.[8-10] Questionnaires were mailed to 5967 twin pairs aged ≥18 years. Ages of respondents then ranged from 18 to 88 years. After one or two reminders to nonrespondents, completed questionnaires were returned by both members of 3808 twin pairs (64% pairwise response rate). A two-item zygosity questionnaire was used to determine zygosity for same-sex pairs.[8] Such questionnaires have been shown to give at least 95% agreement with diagnosis on the basis of extensive blood typing.[11, 12]

Twins who were menstruating regularly at the time of survey were asked about cycle length, duration of

6/1/36037

menstrual periods, flow, pain, and limitation related to menstruation. Twins who had stopped menstruating were asked whether this was due to hysterectomy, menopause, or some other cause and at what age it occurred. Wave 1 variables tested for association with subsequent hysterectomy status were oral contraceptive use and duration of use, age at menarche, history of pregnancy, total pregnancies, age at first pregnancy, terminations of pregnancy, days of menstrual bleeding, self-ratings (three-point scales) of heaviness of menstrual flow, menstrual pain, and whether menstruation was limiting, average menstrual cycle length, and number of obstetric difficulties experienced, DSSI/sA (Delusions-Symptoms-States Inventory/States of Anxiety and Depression) anxiety and depression scores,[13] Extraversion and Neuroticism scores,[14] educational attainment, and history of smoking.

Wave 2 (1988 through 1990). Between 1988 and 1990, twin pairs who had responded to the wave 1 survey were traced and relocated for follow-up. The second questionnaire replicated many of the earlier questions, including that on hysterectomy, and included some new items on premenstrual syndrome and other potential risk factors. This two-wave design allowed us to consider wave 1 variables prospectively as possible "risk factors" for subsequent hysterectomy. Wave 2 variables tested for association with hysterectomy were premenstrual symptom interference in usual activities, self-diagnosis of "premenstrual syndrome or premenstrual tension," whether treatment had ever been sought for premenstrual problems, perception of own social class, total Parental Bonding Instrument (PBI) score[15] and PBI factor scores on parental coldness, overprotection, and discouragement of child's autonomy, and total number of life events from a series of items including experience of rape or sexual assault and loss of a pregnancy or a child.

Twin pair correlations. We assume that hysterectomy is performed when a threshold is crossed on an underlying continuum of symptoms. These symptoms have many (multifactorial) causes; therefore it is reasonable to assume that the continuum is normally distributed. It is much more informative to consider the correlation between relatives for the continuous trait, or *liability*, than for the simple dichotomy of presence or absence of hysterectomy. The appropriate statistic that estimates this correlation in liability between twins is the *polychoric correlation*, of which the special case for two dichotomous variables is the tetrachoric correlation. These may be calculated with the PRELIS 1.12 software system.[16]

Results

Response. Responses to wave 1 were received from 1983 complete female pairs (1232 monozygotic and 751 dizygotic), and 1448 (921 monozygotic and 527 dizygotic) also answered the hysterectomy question at wave 2 (76% of pairs where both twins were still alive). Of the 366 women reporting hysterectomy at wave 1, 339 also completed the wave 2 survey. A total of 564 hysterectomies was reported over the two waves (366 at wave 1 and a further 198 at wave 2), 475 being in responding pairs at wave 2 (319 monozygotic and 156 dizygotic pairs). Pairwise concordance for hysterectomy for twins born before 1947 in wave 1 was 34.1% for monozygotic twins and 15.7% for dizygotic twins. At wave 2, for twins born before 1955, pairwise concordance was 39.4% for monozygotic twins and 21.4% for dizygotic twins. At wave 1 only 17 hysterectomies were reported by women born after 1946, and at wave 2 only five were reported by women born after 1954.

Twins who had undergone hysterectomy were asked in both questionnaires how old they were when they had the operation and in the wave 2 questionnaire whether the hysterectomy was before, during, or after menopause and whether both ovaries were removed. The mean ± SD for age at hysterectomy in wave 2 was 40.4 years ± 7.9, with a range of 18 to 76 years. Most hysterectomies were performed between the ages of 34 and 43 years (53%), so most women (77%) underwent hysterectomy before menopause.

Survival analysis. Hysterectomy increases in incidence with age but, as previously discussed, prevalence has also varied for secular reasons including changes in surgical fashion and health financing. Both these temporal effects may differentially affect the importance of genetic and environmental influences on hysterectomy, and it is important to try to disentangle them. Fortunately, the two-wave design of our study gives some scope for this. It is also important to ensure that any such temporal effects are similar in the monozygotic and dizygotic subsamples.

Survival to age at hysterectomy was calculated for twins in the two study waves. The most powerful test of secular change in hysterectomy rates was comparison of women aged ≥40 in wave 1 (born before 1940) with those in the same age group at wave 2 (born before 1948). There was overlap in the two samples, because women born before 1940 who responded to wave 2 were also in the second sample. Nevertheless, we see a marked secular increase in hysterectomy rates (Fig. 1) in the wave 2 sample (Lee-Desu $\chi^2_1 = 9.49$, $p = 0.002$). There was no heterogeneity in survival to hysterectomy between older (>40 years) monozygotic and dizygotic twins at wave 1 ($\chi^2_1 = 2.76$, $p = 0.10$) or wave 2 ($\chi^2_1 = 0.89$, $p = 0.35$).

Twin correlations. Because hysterectomy incidence varies with age and also for secular reasons, we tabulated the tetrachoric correlations (and their asymptotic standard errors) for liability to hysterectomy in monozygotic and dizygotic twins for three age bands (34 to 40, 41 to 48, and >48 years) and for the total sample

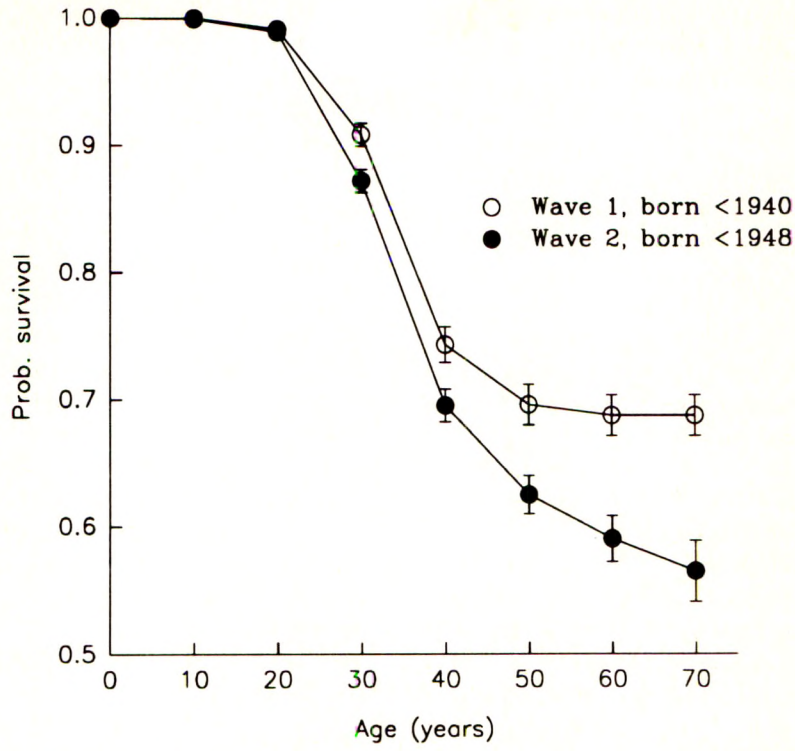

Fig. 1. Probability of reaching given age without hysterectomy in women aged >40 in waves 1 and 2.

(aged >33 years) in both waves of the study (Table I). The first point to notice is that correlations are remarkably consistent between waves for the same age band, and this gives us confidence that secular changes in incidence have little effect on twin correlations. Second, the monozygotic correlations are remarkably consistent (around 0.6) in all age bands. In contrast, the dizygotic correlations appear to increase from the oldest to the youngest age band, although the standard errors are large.

Pearson correlations for age at hysterectomy within pairs concordant for hysterectomy at wave 2 suggested that genetic influence might be operating on the timing of hysterectomy ($r = 0.49 \pm 0.11$ for monozygotic and $r = 0.15 \pm 0.22$ for dizygotic), as well as on "liability" to hysterectomy. This was not apparent at wave 1, because monozygotic and dizygotic correlation coefficients were of equal magnitude ($r = 0.50 \pm 0.14$ for monozygotic and $r = 0.50 \pm 0.25$ for dizygotic), suggesting that variation might be due to environmental influences only. Note, however, that numbers are small (Table I) and that there were only 17 concordant dizygotic pairs at wave 1.

Model fitting to test for heterogeneity. The decline

in the dizygotic correlation for hysterectomy liability with increasing age suggests that the relative importance of genetic and environmental influences may also vary with age, genetic factors becoming more important in older women. To test this formally, we used LISREL 7.16[17] software to fit models of variation simultaneously to monozygotic and dizygotic correlations for the three age bands. Variance disaggregates into three components: additive gene action *(h)*, environmental influences specific to the individual *(e)*, and either environmental effects common to both cotwins *(c)* or nonadditive gene action *(d)* (for example, dominance or epistasis).

Fitting the simplest model consistent with the observed correlations (comprising only h and e) to the three cohorts in wave 1 resulted in a very good fit ($\chi^2_5 = 5.47$). Adding shared environment ($\chi^2_4 = 5.47$) or nonadditivity ($\chi^2_4 = 4.41$) did not significantly improve fit, and dropping gene action from the model (c and e, no h) significantly worsened fit ($\chi^2_5 = 14.88$, $p = 0.011$). Also with wave 2, models fitted to the three birth cohorts simultaneously resulted in a best-fitting simple model comprising h and e ($\chi^2_5 = 1.35$). Again, fit significantly worsened when h was dropped (ce model $\chi^2_5 = 11.09$, $p = 0.05$). These results are not consistent with the existence of heterogeneity in genetic and environmental effects between older and younger twins. Estimates of heritability of liability were consistent across study waves ($h^2 = 0.56$ for wave 1 and $h^2 = 0.59$ for wave 2), affirming that genetic predisposition to hysterectomy was stable and not influenced by changing environmental influences. Any significant influence of shared environment was also rejected.

Covariates of hysterectomy. Polychoric correlations were computed between the potential risk factors in Methods and post–wave 1 hysterectomy. Wave 2 reports of whether premenstrual symptoms ever interfered "with work, daily activities, usual social events or . . . relationships with others" (retrospective) were the most highly correlated with hysterectomy. All significant covariates are presented in Table II. Hypotheses concerning preexisting psychologic morbidity and experiences of loss in women undergoing hysterectomy were not supported by our data.

Twins discordant for hysterectomy. Discordant twin pairs, especially monozygotic pairs, provide an ideal case-control design. Variables hypothesized as precursors of hysterectomy were tested for the 106 twin pairs discordant for "new" hysterectomy, where one twin had a hysterectomy after the wave 1 survey and her cotwin had not had a hysterectomy by wave 2 (see Table III). "New" hysterectomy was selected because the two-wave design allowed for characteristics reported at wave 1 to be reported independently of the subsequent operation. We performed t tests on continuous variables. Fisher's exact test was used on contingency tables to detect significant differences in rates of endorsement of extreme values of categoric variables (for example, "very painful" menses vs "moderately painful" or "no trouble").

Table II. Significant wave 1 covariates* of subsequent hysterectomy in twins born before 1955

Covariate	*r*
1. Premenstrual syndrome symptoms interfered ever†	0.28
2. Limitation by menstruation	0.23
3. Menstrual flow	0.22
4. Average length of menses (days of bleeding)	0.19
5. Menstrual pain (dysmenorrhea)	0.17
6. No. of obstetric problems	0.15
7. Length of average menstrual cycle	−0.08
8. Neuroticism score	0.06
9. Education level	−0.05

*Sample size of 1530 to 2263. All correlations significant at $p < 0.001$ level except 7 and 8 ($p < 0.01$) and 9 ($p < 0.05$).
†Reported retrospectively at wave 2.

In discordant pairs, liability to hysterectomy was associated with the extreme category of "very painful" periods (odds ratio 9.99, 95% confidence interval 2.58 to 38.89). Also risk factors, but to a lesser extent, were the extreme categories of retrospectively reported interference of premenstrual symptoms in usual activities ("a lot") (odds ratio 5.64, 95% confidence interval 1.70 to 18.68), having ever suffered from premenstrual syndrome (odds ratio, 2.04, 95% confidence interval 1.05 to 4.05), previous "heavy" menstrual flow (odds ratio 2.19, 95% confidence interval 1.04 to 4.58), and having ever sought treatment for premenstrual syndrome (odds ratio 2.08, 95% confidence interval 1.00 to 4.41). Reporting "very limiting" periods (odds ratio 3.24, 95% confidence interval 0.74 to 14.15) was not a significant risk factor.

Multivariate path analysis. To see how much of the variance in liability to hysterectomy could be explained by these covariates, a simple multivariate path model was fitted with LISREL software (Fig. 2). The influence of particular variables may appear inconsistent with the odds ratios reported previously because the highest odds ratios were found for the rarest events (i.e., those with least frequent endorsement) and in the path analysis the entire distributions are entered. Our path model had the advantage of specifying one-way effects from the possible risk factors to the underlying risk of hysterectomy and ipso facto of addressing the latent variable rather than only the observed event. We were unable to explain satisfactorily the basis of the genetic variance in liability to hysterectomy by identifying genetic and environmental influences on reported risk factors. The major covariates of hysterectomy measured in our study accounted for only 15% of the phenotypic variance in liability to hysterectomy. Cholesky

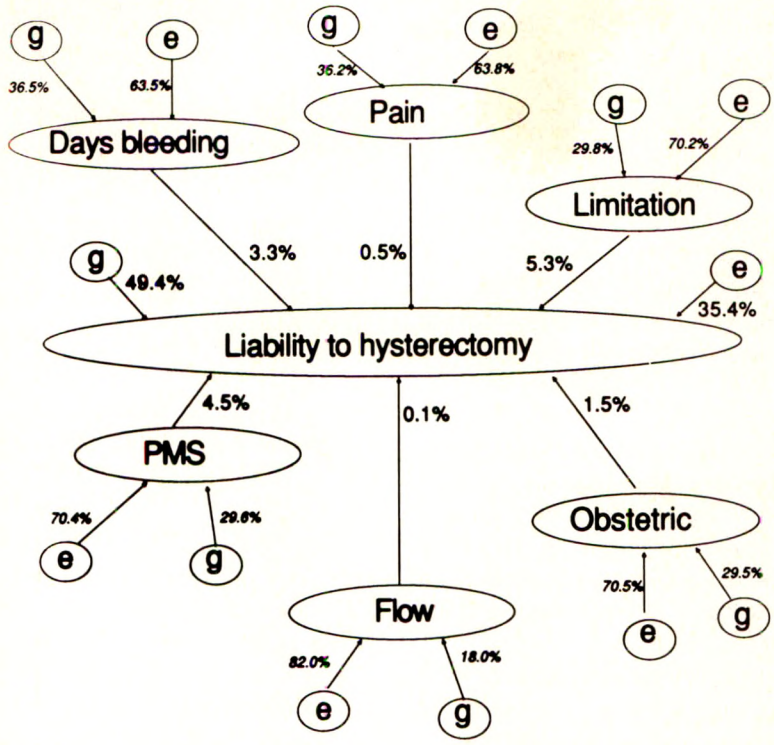

Fig. 2. Path model for causes of variation in liability in hysterectomy. Genetic and unique environmental sources of variation specific to each variable are denoted *g* and *e*. Paths between measured variables denote direct phenotypic influence. Percentages on paths indicate percent of variance in target variable contributed by each source.

saturation of the model to allow for all intercorrelations[18, 19] similarly revealed no notable genetic loading of hysterectomy on other risk factors but considerable environmental loading (data not shown). Thus genetic influences on liability to hysterectomy can be ascribed only in small part (perhaps 10%) to genetic influences on identified risk factors, so the major heritable factors are yet to be identified.

Comment

We have found clear evidence of genetic influences on liability to hysterectomy. These influences are stable across birth cohorts in which there are differences in incidence because of both aging and secular changes in surgical practice and health financing. Our analysis of reported risk factors has not revealed the basis of the largest part (85%) of the variance in liability to hysterectomy, and at least half of this is due to unidentified genetic factors. Extent of perceived interference of premenstrual problems, accounting for <5% of variance, was ahead of other menstrual dysfunction variables as risk factors for hysterectomy. The personality trait Neuroticism was barely a significant covariate and certainly played no notable role in explaining the variance. Measures of depression and anxiety proved to have no explanatory relevance. Our findings do not support the important role of these psychologic dimensions in risk for hysterectomy claimed by some authors.[6, 7]

Central to our interpretation of higher monozygotic than dizygotic twin correlations as evidence for genetic influence on hysterectomy liability is the assumption that monozygotic twins experience environmental treatments no more similarly than their dizygotic counterparts, at least insofar as these treatments pertain to the trait in question, in this case hysterectomy. This "equal environments assumption" has been challenged on the grounds that there is indeed a higher "environmental" correlation between monozygotic than dizygotic twin pairs. Evidence suggests, however, that any such effect arises because monozygotic twins, being genetically identical, create more similar environments for themselves.[20-22] If some monozygotic twins were becoming concordant for hysterectomy from frivolous reasons of imitation rather than genuine medical need, one might expect the prevalence to be higher in monozygotic than dizygotic twins; however, as our survival analysis shows, there is no significant difference in the rates of the two zygosity groups. This does not support the possibility either that physicians might have treated adult dizygotic twins (as individuals) differently from monozygotic twins or that monozygotic twin pairs were

Table III. Significant differences in pairs who became discordant for hysterectomy between wave 1 and wave 2

	Discordant pairs (H^+H^-)

H^+, Hysterectomy present; H^-, hysterectomy absent.

more likely to be referred to the same specialist as dizygotic twin pairs. Similarly, the argument that, if the increased dizygotic twinning in older mothers is genetically influenced, there might be selection against earlier hysterectomy in dizygotic twins compared with monozygotic twins is not supported by the similar age-at-hysterectomy distributions in the two zygosity groups.

Limitations of the study demanding acknowledgement are: (1) data censoring, (2) validity of self-reporting, and (3) representativeness of the sample. Using twin pairs discordant for recent hysterectomy increases the likelihood of the cotwin having a future (and yet-to-be-reported) hysterectomy after wave 2. Analysis of hysterectomy, like analysis of many procedures, events, or illnesses of importance to epidemiologists, is influenced by the problem of timing of onset, leading to data censoring.[23] Only if subjects were assessed at death could the exact lifetime prevalence of hysterectomy be known. The approach of Neale et al.[24] will be used in future analyses to deal with the problem, which has also arisen in analyses of appendectomy[25] and tonsillectomy[26] twin data.

All variables were measured by self-report; hysterectomy was not validated by the twin in person, her cotwin, or a medical practitioner. For most women, however, hysterectomy would be a noteworthy event requiring hospitalization and therefore would likely be more accurately reported than less well-defined medical conditions. The wave 1 questionnaire actually stated that hysterectomy was "removal of the womb." In support, none of the twins who answered "no" to hysterectomy at wave 2 had said "yes" at wave 1. When age at hysterectomy was reported at both waves, the Pearson correlation for the two reports was $r = 0.94$ ($p < 0.001$), suggesting acceptable consistency in reporting over an average of 8 years.

The twin sample has been shown to be representative of the Australian population on a number of variables, such as drinking behavior,[27] personality factors, and anxiety and depression.[8, 20] The wave 1 sample was unselected for anything except volunteering to enroll in the Australian National Health and Medical Research Council Twin Register and returning the questionnaire. On the basis of age-specific hysterectomy rates in the Australian State of New South Wales in 1983, the expected cumulated total proportion of women having lost a uterus was 29% (25% for a 65-year-old woman).[2] Our cumulated risk of hysterectomy in the wave 1 sample (1980 through 1982) was 31% at age 65, a higher but comparable proportion. At wave 2 the cumulated risk was 41% at age 60, reaching a maximum of 43%, which is higher than might be expected from 1983 projections, although the modal year of wave 2 data collection was 1989, for which we have no normative data and numbers were relatively small in these older age groups.

We intend to include medical and pathology records relating to hysterectomy in further analysis to help elucidate the sources of genetic influence. We need to compare the distribution of indications for the hysterectomies in monozygotic and dizygotic twins. Clinical symptoms presented to twins' medical practitioners may have differed from the self-reported characteristics assessed in this study. Hysterectomy may have followed wave 1 reports by between 1 and 8 years; therefore there may be considerable heterogeneity in our sample in the relationship with antecedent "risk factors." Lack of consensus concerning recognition and significance of medical indications may make retro-

spective interpretation difficult.[3] Nevertheless, we plan to gather information on indications and the twins' reasons for hysterectomy in a new phase of the study. The power of our findings will be further tested by analysis of data being collected on hysterectomy from these twins' mothers, sisters, and adult daughters and from female relatives of male twins in the Australian Twin and Family Study.

We thank Dr. Rosemary Jardine and Marilyn Olsen for assistance with wave 1 data collection, and Ulrich Kehren, Olivia Zheng, Joanne Caldwell, Sue Mason, and all team members for assistance with wave 2 data collection. We also thank Dr. David Duffy for help with data analysis.

NORPLANT® SYSTEM
levonorgestrel implants

Lasts 5 years...yet is reversible

Serious as well as minor side effects may occur. The most common side effect which has been observed is menstrual bleeding irregularities.

Please see brief summary of prescribing information on the following page.

©1992, Wyeth-Ayerst Laboratories. 70443C

NORPLANT® SYSTEM
levonorgestrel implants
Lasts five years…yet is reversible

BRIEF SUMMARY OF PRESCRIBING INFORMATION. CONSULT THE PACKAGE LITERATURE FOR FULL PRESCRIBING INFORMATION.

Indications and Usage

The NORPLANT SYSTEM is indicated for the prevention of pregnancy and is a long-term (up to 5 years) reversible contraceptive system. The capsules should be removed by the end of the 5th year. New capsules may be inserted at that time if continuing contraceptive protection is desired.

Contraindications

1. Active thrombophlebitis or thromboembolic disorders. 2. Undiagnosed abnormal genital bleeding. 3. Known or suspected pregnancy. 4. Acute liver disease; benign or malignant liver tumors. 5. Known or suspected carcinoma of the breast.

Warnings

A. WARNINGS BASED ON EXPERIENCE WITH THE NORPLANT SYSTEM

1. *Bleeding Irregularities* — Most women can expect some variation in menstrual bleeding patterns. Irregular menstrual bleeding, intermenstrual spotting, prolonged episodes of bleeding and spotting, and amenorrhea may occur, and could mask symptoms of cervical or endometrial cancer. Overall, these irregularities diminish with continued use. Because amenorrhea may occur, missed menstrual periods cannot serve as the only identifier of early pregnancy. Perform pregnancy tests whenever pregnancy is suspected. If pregnancy occurs, the capsules must be removed. Hemoglobin concentrations found in clinical trials generally indicated that reduced menstrual blood loss is associated with NORPLANT SYSTEM use. Blood loss resulting in hemoglobin values consistent with anemia occurred rarely.

2. *Delayed Follicular Atresia* — Atresia of the follicle is sometimes delayed, resulting in enlarged follicles that are clinically indistinguishable from ovarian cysts. In the majority of women, enlarged follicles disappear spontaneously. Rarely, they twist or rupture and surgical intervention may be required.

3. *Ectopic Pregnancies* — Ectopic pregnancies have occurred among NORPLANT SYSTEM users, although clinical studies have shown no increase in the rate of ectopic pregnancies per year among NORPLANT SYSTEM users as compared with users of no method or of IUDs. The incidence among NORPLANT SYSTEM users (1.3 per 1000 woman-years) was significantly below the rate estimated for noncontraceptive users in the U.S. (2.7 to 3.0 per 1000 woman-years). Ectopic pregnancy risk may increase with duration of NORPLANT SYSTEM use and increased weight of the user. Rule out ectopic pregnancy in any patient presenting with lower-abdominal pain.

4. *Breast-feeding* — Steroids are not the contraceptives of first choice for lactating women. Levonorgestrel has been identified in breast milk. Limited data suggests no significant effects on infant growth or health when mothers used the NORPLANT SYSTEM beginning 6 weeks after parturition.

5. *Foreign-body Carcinogenesis* — Rarely, cancers occur at foreign-body intrusion sites or old scars. None has been reported in NORPLANT SYSTEM clinical trials and risk to users is judged to be minimal.

6. *Thromboembolic Disorders* — Remove capsules if active thrombophlebitis or thromboembolic disease develops. With prolonged immobilization removal should be considered.

B. WARNINGS BASED ON EXPERIENCE WITH COMBINATION (PROGESTIN PLUS ESTROGEN) ORAL CONTRACEPTIVES (OCs)

Note: Many of the side effects or risks listed below are thought to be estrogen-related; the association of the NORPLANT SYSTEM progestin-only method to these risks is unknown.

1. *Cigarette Smoking* — Cigarette smoking increases the risk of serious cardiovascular side effects from combined OC use. Risk increases with age and heavy smoking (≥15 cigarettes/day) and is quite marked in women over 35 years old.

2. *Elevated Blood Pressure* — Increase in blood pressure has been reported in combination OC users; prevalence increases with long exposure.

3. *Thromboembolic Disorders and Other Vascular Problems* — An increased risk of thromboembolic and thrombotic disease is associated with combination OC use. Estimate of relative risk is 4- to 11-fold higher for users vs. nonusers.

Cerebrovascular Disorders: Combination OCs increase the relative and attributable risk of cerebrovascular events (thrombotic and hemorrhagic strokes). Generally, risk is greatest among hypertensive women > 35 years of age who smoke.

Myocardial Infarction (MI): An increased risk of MI has been attributed to combined OC use. This is thought to be primarily thrombotic in origin and related to the estrogen component. Increased risk occurs primarily in smokers or women with other underlying risk factors for coronary-artery disease. Relative risk of heart attack for combined OC users is estimated as 2 to 6 times that for nonusers. Absolute risk is very low for women under 30 years old.

Studies indicate a significant trend toward higher MI and stroke rates with increased progestin doses in combination OCs. However, recent data indicated no increased MI risk with past use of levonorgestrel-containing OCs.

4. *Carcinoma* — Recent evidence in the literature suggests no association between OC use and increased risk of breast cancer in the overall population of users. The Cancer and Steroid Hormone (CASH) study also showed no latent effect on breast cancer risk for at least a decade following long-term use. Some of these same studies have shown an increased relative risk of breast cancer in certain subgroups; no consistent pattern has been identified. Some studies suggest an association between combination OCs and an increase in the risk of cervical intra-epithelial neoplasia in some populations of women. The extent to which such findings may be due to differences in sexual behavior and other factors remains controversial. A cause-and-effect relationship between combined OC use and breast or cervical cancer has not been established. Combination OCs may decrease ovarian and endometrial cancer risk. Irregular bleeding patterns associated with NORPLANT SYSTEM use could mask cervical or endometrial cancer symptoms.

5. *Hepatic Tumors* — Hepatic adenomas are associated with combination OC use; estimated incidence is 3 events per 100,000 users per year. Risk increases after 4 or more years of use. Hepatic adenomas are benign but may rupture and cause death through intra-abdominal hemorrhage.

6. *Ocular Lesions* — Retinal thrombosis is associated with OC use and is believed to be related to the estrogen component. However, NORPLANT SYSTEM capsules should be removed if there is unexplained partial or complete vision loss; onset of proptosis or diplopia; papilledema; or retinal vascular lesions. Undertake appropriate diagnostic and therapeutic measures immediately.

7. *Use Before or During Early Pregnancy* — Extensive epidemiological studies reveal no increased risk of birth defects when OCs are used prior to pregnancy. Studies also do not suggest a teratogenic effect when taken inadvertently during early pregnancy. No evidence suggests that risk with NORPLANT SYSTEM use is different.

8. *Gallbladder Disease* — Early studies reported an increased lifetime relative risk of gallbladder surgery in OC or estrogen users. More recent studies, however, indicate that the relative risk of gallbladder disease with OC use may be minimal; this may be related to use of OCs with less estrogen and progestin content.

Precautions

GENERAL:

1. *Physical Examination and Follow-up* — A complete medical history and physical examination should be taken prior to implantation or reimplantation of NORPLANT SYSTEM capsules and at least annually during its use. Exams should include special reference to the implant site, blood pressure, breasts, abdomen and pelvic organs, including cervical cytology and relevant laboratory tests. Rule out malignancy in cases of undiagnosed, persistent or recurrent abnormal vaginal bleeding. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care.

2. *Carbohydrate Metabolism* — Altered glucose tolerance is found in some combination and progestin-only OC users. Effects of NORPLANT SYSTEM on carbohydrate metabolism appear minimal. Observe diabetic and prediabetic patients carefully while using the NORPLANT SYSTEM. Follow women being treated for hyperlipidemias closely if using the NORPLANT SYSTEM. Some progestins may elevate LDL and may render control of hyperlipidemias more difficult. (See **Warnings**.)

3. *Liver Function* — Consider removing capsules if jaundice develops. Steroid hormones may be poorly metabolized in patients with impaired liver function.

4. *Fluid Retention* — Steroid contraceptives may cause some degree of fluid retention. Prescribe with caution, and careful monitoring, in patients with conditions possibly aggravated by fluid retention.

5. *Emotional Disorders* — Consider removing capsules if significant depression occurs since the symptom may be drug-related. Observe carefully those with history of depression and consider removal if depression recurs to a serious degree.

6. *Contact Lenses* — Contact-lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist.

7. *Insertion and Removal* — Insertion is advised during the first 7 days of the cycle or immediately following abortion to insure that the woman is not pregnant and to assure contraceptive effectiveness during first cycle of use. Capsules may be inserted at any time during the cycle provided pregnancy has been excluded and a nonhormonal contraceptive method is used for the remainder of the cycle. Insertion is not recommended before 6 weeks postpartum in breast-feeding women. Follow insertion and removal instructions closely. Healthcare professionals are strongly advised to be instructed in the procedures before they attempt them. Proper insertion just under the skin facilitates removals; proper insertion and removal should result in minimal scarring. If all capsules cannot be removed at first attempt, attempt removal later when the site has healed. Bruising may occur at implant site during insertion or removal. Hyperpigmentation may occur over implant site but is usually reversible following removal. **See Full Prescribing Information for Detailed Insertion/Removal Instructions.**

8. *Infections* — Implant site infection has been uncommon (0.7%); aseptic technique and proper insertion/removal reduces possibility of infection. Institute treatment if infection occurs; remove capsules if infection persists.

9. *Expulsion* — Expulsion of capsules was uncommon; frequency increased when capsule placement was extremely shallow, was too close to incision, or when infection was present. Replace expelled capsule with new sterile capsule. Treat and cure any infection before replacement. Contraceptive efficacy may be inadequate with fewer than 6 capsules.

10. *Provisions for Removal* — Advise women that capsules may be removed at any time for any reason. Personnel instructed in removal technique should perform removal on request or at the end of 5 years of usage. Upon removal, dispose of capsules in accordance with Centers for Disease Control Guidelines for biohazardous waste.

DRUG INTERACTIONS: Reduced efficacy (pregnancy) in NORPLANT SYSTEM users has been reported when phenytoin or carbamazepine were used concomitantly. Warn NORPLANT SYSTEM users of possible decreased efficacy with use of related drugs.

DRUG/LABORATORY TEST INTERACTIONS: 1. Sex-hormone-binding globulin concentrations are decreased. 2. Thyroxine concentrations may be slightly decreased and triiodothyronine uptake increased.

CARCINOGENESIS: See **Warnings** section and Full Prescribing Information.

PREGNANCY: Pregnancy Category X. See **Warnings** section and Full Prescribing Information.

NURSING MOTHERS: See **Warnings** section and Full Prescribing Information.

INFORMATION FOR THE PATIENT: See Patient Labeling. Provide copy of patient labeling to the patient. Advise patients that Prescribing Information is available upon request. Inform prospective users of risks and benefits associated with NORPLANT SYSTEM use, with other forms of contraception, with no contraception, and about insertion/removal procedures. Informed consent from all patients may be desired in light of techniques involved with insertion and removal.

Adverse Reactions

The following have been associated with the NORPLANT SYSTEM during first year of use: many bleeding days or prolonged bleeding (27.6%); spotting (17.1%); amenorrhea (9.4%); irregular (onsets of) bleeding (7.6%); frequent bleeding onsets (7.0%); scanty bleeding (5.2%); pain or itching near implant site - usually transient - (3.7%); infection at implant site (0.7%); removal difficulties affecting subjects - based on 849 removals - (6.2%).

Controlled clinical studies suggest that the following, occurring during the first year, are probably associated with NORPLANT SYSTEM use: headache; nervousness; nausea; dizziness; adnexal enlargement; dermatitis; acne; change of appetite; mastalgia; weight gain; hirsutism, hypertrichosis, and scalp-hair loss. The following were reported with a frequency of 5% or greater during the first year and possibly may be related to NORPLANT SYSTEM use: breast discharge; cervicitis; musculoskeletal pain; abdominal discomfort; leukorrhea; vaginitis.

Overdosage

Overdosage may cause fluid retention with its associated effects and uterine bleeding irregularities.

Dosage and Administration

The NORPLANT SYSTEM consists of six Silastic® capsules, each containing 36 mg of the progestin, levonorgestrel. The total administered (implanted) dose is 216 mg. Implantation of all six capsules should be performed during the first 7 days of the onset of menses by a healthcare professional instructed in the NORPLANT SYSTEM insertion technique. Insertion is subdermal in the midportion of the upper arm about 8 to 10 cm above the elbow crease. Distribution should be in a fanlike pattern, about 15 degrees apart, for a total of 75 degrees. Proper insertion will facilitate later removal. **(See Full Prescribing Information for Detailed Insertion/Removal Instructions.)**

Maternal and fetal hemodynamic effects of autologous blood donation during pregnancy

Sabine Droste, MD,[a] Tanya Sorensen, MD,[b] Thomas Price, MD,[c] Merlin Sayers, MD,[c] Thomas Benedetti, MD,[b] Thomas Easterling, MD,[b] and Susan Hendricks, MD[b]

Madison, Wisconsin, and Seattle, Washington

OBJECTIVES: Our objectives were to describe the maternal and fetal hemodynamic impact of a 1 U acute blood loss during pregnancy and to compare the hemodynamic responses of pregnant women with those of nonpregnant controls.

STUDY DESIGN: With Doppler techniques cardiac output and total peripheral vascular resistance were determined in 16 pregnant women in the third trimester and in 16 nonpregnant volunteers before and during orthostatic stress, before and after donation of 450 ml of whole blood. In pregnant women the fetal umbilical artery systolic/diastolic ratio was also determined. Data were subjected to multiple logistic regression analysis.

RESULTS: In both groups orthostasis provoked significant decreases in cardiac output and increases in total peripheral vascular resistance. The hemodynamic effects of blood loss were less pronounced and did not significantly change the hemodynamic response to orthostasis in either group. Neither orthostasis nor blood loss caused significant changes in the umbilical systolic/diastolic ratio.

CONCLUSION: These data support the hemodynamic safety of uncomplicated autologous blood donation during late pregnancy. (Am J Obstet Gynecol 1992;167:89-93.)

Key words: Hemodynamics, autologous blood donation, pregnancy

The precise hemodynamic impact of a 1 U acute blood loss on systemic and fetoplacental perfusion has not been described in normal human pregnancy or in nonpregnant individuals. Outcome measures such as vital signs and the frequency of vasovagal episodes or fetal parameters such as Apgar score, birth weight, and frequency of fetal distress are crude and too easily influenced by factors other than those directly related to phlebotomy. However, methods now exist to study both the maternal and fetoplacental circulatory beds in a noninvasive and reproducible fashion.

The collection, storage, and use of autologous blood during the third trimester of pregnancy have been described since 1969.[1] Predonation and use of autologous blood is thought by some to be underused in the general population scheduled for elective surgery.[2] Although autologous blood donation appears to be gaining in overall popularity,[3] its utility in the pregnant population at risk for excessive obstetric blood loss remains under considerable debate.[4-6] Analysis of older case reports[1, 7, 8] and more recent published series[9-12] of autologous blood donation and administration during pregnancy appears to confirm the overall clinical safety of this blood banking technique. However, few if any cases have been studied in sufficient detail to permit conclusions about hemodynamic consequences of autologous donation other than maternal and fetal pulse and maternal blood pressure.

We report the results of a prospective study designed to characterize in some detail the maternal and fetal hemodynamic effects of the loss of 1 U of whole blood obtained for autologous use during the third trimester of pregnancy. These hemodynamic effects are compared with those observed in an age-matched cohort of nonpregnant female volunteer blood donors.
